At the time of presentation, the clinician should address the need for follow-up care, including psychological counseling. Adolescent victims are at increased risk of posttraumatic stress disorder, depression, self-abusive behaviors, suicidal ideation, delinquency, substance abuse, eating disorders, and sexual revictimization. It is important for the adolescent victim and parents to understand the value of timely counseling services to decrease these potential long-term sequelae. Counseling services should be arranged during the initial evaluation, with follow-up arranged with the primary care physician to improve compliance. Counseling services for family members of the victim may improve their ability to provide appropriate support to the adolescent victim. Caution parents not to use the assault as a validation of their parental guidance, as it will only serve to place blame inappropriately on the adolescent victim.

**PREVENTION**

Primary prevention may be accomplished through education of preadolescents and adolescents on the issues of rape, healthy relationships, Internet dangers, and drug-facilitated rape. Prevention messages should be targeted to both males and females at high schools and colleges. Particular emphasis on prevention efforts during college orientation is highly recommended. High-risk situations that may increase the likelihood of a sexual assault (use of drugs or alcohol) should be discouraged. Secondary prevention includes informing adolescents of the benefits of timely medical evaluations when rape has occurred. Individual clinicians should ask adolescents about past experiences of forced and unwanted sexual behaviors and offer help in dealing with those experiences. The importance of prevention cannot be overstated because adolescents are disproportionately affected by rape and they are particularly vulnerable to long-term consequences.

Bibliography is available at Expert Consult.
Age-specific rates of many sexually transmitted infections (STIs) are highest among sexually experienced adolescents and young adults, after controlling for sexual activity. Although some STI pathogens present as STI syndromes with a specific constellation of symptoms, most are asymptomatic and only detected by a laboratory test. The approach to prevention and control of these infections lies in education, screening, and early diagnosis and treatment.

**ETIOLOGY**

Any adolescent who has had oral, vaginal, or anal sexual intercourse is at-risk for acquiring an STI. Not all adolescents are at equal risk; physical, behavioral, and social factors contribute to the adolescent’s higher risk (Table 120-1). Adolescents who initiate sex at a younger age, youth residing in detention facilities, youth attending sexually transmitted diseases clinics, young men having sex with men, and youth who are injecting-drug users are at higher risk for STIs. Risky behaviors, such as sex with multiple concurrent partners or multiple sequential partners of limited duration, failure to use barrier protection consistently and correctly, and increased biologic susceptibility to infection, also contribute to risk. Although all 50 states and the District of Columbia explicitly allow minors to consent for their own sexual health services, many adolescents encounter multiple obstacles to accessing this care. Adolescents who are victims of sexual assault may not consider themselves “sexually active,” given the context of the encounter, and need reassurance, protection, and appropriate intervention when these circumstances are uncovered (see Chapter 119).

**EPIDEMIOLOGY**

STI prevalence varies by age, gender, and race/ethnicity. In the United States, although adolescents and young adults ages 15-24 yr represent 25% of the sexually experienced population, this age group accounts for nearly 50% of all incident STIs each year. Adolescents and young adults <25 yr of age have the highest reported prevalence of gonorrhea (see Chapter 192) and chlamydia (see Chapter 226) infection; among females and males, rates are highest in the 15-24 yr old age groups (Fig. 120-1). In 2012, females 20-24 yr of age had the highest reported chlamydia rate (3,696 per 100,000 population), followed by females 15-19 yr of age (3,293 per 100,000 population). The reported 2012 chlamydia rate for 15-19 yr old females was more than 4 times higher than for 15-19 yr old males. Chlamydia is common among all races and ethnic groups; Blacks, Native American/Alaska Native, and Hispanic females are disproportionately affected. In 2011, non-Hispanic black females 20-24 yr of age had the highest chlamydia rate of any group (7,863), followed by black females 15-19 yr of age (7,719). Data from the 2007-2008 National Health and Nutrition Examination Survey estimated the prevalence of chlamydia among the U.S. population was highest among African-Americans (Fig. 120-2).

Reported rates of other bacterial STIs are also high among adolescents and young adults. In 2012, 20-24 yr old females had the highest (579 per 100,000 population) and 15-19 yr old females had the second highest gonorrhea rates (521 per 100,000 population) compared to any other age/sex group (see Chapter 192). Following a period of decreasing gonorrhea rates among 20-24 yr old, rates have increased for the past 3 yr. Primary and secondary syphilis rates among 15-19 yr old...
females have decreased annually since 2009 from 3.3 cases per 100,000 population to 2.3 per 100,000 population in 2012 (see Chapter 218). Rates among females have been the highest each year in the 20-24 yr age group (3.9 cases per 100,000 population in 2012). Primary and secondary syphilis rates among 15-19 yr old males are much lower than those in older males, although rates among males age 20-24 yr have increased consecutively since 2002, from 5.2 cases per 100,000 males to 23.4 cases in 2011. Males age 20-24 yr also have had the highest rate of primary and secondary syphilis among males of any age group since 2008. Pelvic inflammatory disease (PID) rates are highest in females age 15-24 yr when compared to older women.

Adolescents also suffer from a large burden of viral STIs. Young people in the United States are at persistent risk for HIV infection (see Chapter 278). In 2009, youths age 13-24 yr, who represented 21% of the U.S. population, comprised 7% of persons living with HIV. In 2010, 26% of the estimated 47,500 new HIV infections were among 13-24 yr olds. Of those new infections, 57% were among blacks, 20% among Hispanic/Latinos, and 20% among whites. Nearly 75% of the 12,200 new HIV infections among youths were attributable to male-to-male sexual contact. Only a low percentage of youths have been tested for HIV, and 60% of youths with HIV are unaware of their infection.

The STI with the highest estimated incidence in the United States is human papillomavirus (HPV). The 2003-2006 National Health and Nutrition Examination Survey (NHANES) found a third of females age 14-24 yr old were actively infected with HPV. The highest HPV infection prevalence was among females age 20-24 yr (54%; 95% confidence interval [CI], 46-62%; see Chapter 266). Although HPV infection is common, studies suggest approximately 90% of infections clear within 2 yr. Herpes simplex virus-2 (HSV-2) is the most prevalent viral STI (see Chapter 252), HSV-2 prevalence rates among adolescents in the United States and young adults appear to be decreasing. The 2005-2008 NHANES estimated that 1.4% (95% CI, 1.0-2.0) of adolescents age 14-19 yr are infected with HSV-2, which is about a 76% decrease observed from the 1988-1994 NHANES and 10.5% (95% CI, 9.0-12.3) of 20-29 yr olds are HSV-2 seropositive, which is a 39% decrease compared to the 1988-1994 NHANES.

Pathogenesis
During puberty, increasing levels of estrogen cause the vaginal epithelium to thicken and cornify and the cellular glycogen content to rise, the latter causing the vaginal pH to fall. These changes increase the resistance of the vaginal epithelium to penetration by certain organisms (including Neisseria gonorrhoeae) and increase the susceptibility to others (Candida albicans and Trichomonas; see Chapter 284). The transformation of the vaginal cells leaves columnar cells on the ectocervix, forming a border of the 2 cell types on the ectocervix, known as the squamocolumnar junction. The appearance is referred to as ectopy (Fig. 120-3). With maturation, this tissue involutes. Prior to involution, it represents a unique vulnerability to infection for adolescent females. A 15 yr old sexually active female with endocervical colonization has a 1:8 chance of developing PID compared to the 1:80 chance for a 24 yr old. As a result of these physiologic changes, gonococcal infection becomes primarily cervical and susceptibility to ascending infection is greatest during menses, when the pH is 6.8-7.0. The association of early sexual debut and younger gynecologic age with increased risk of STIs supports this explanation of the pathogenesis of infection in young adolescents.

Sexually Transmitted Infection Screening
Early detection and treatment are the primary STI control strategies. Some of the most common STIs in adolescents, including HPV, HSV, chlamydia, and gonorrhea, are usually asymptomatic and if undetected can be spread inadvertently by the infected host. Screening initiatives for chlamydial infections have demonstrated reductions in PID cases by up to 40%. Although federal and professional medical organizations recommend annual chlamydia screening for sexually active females 25 yr and younger, according to the National Center for Quality Assurance, in 2012 approximately 40% of commercially insured and 54% of Medicaid insured 16-20 yr old sexually active females were tested for chlamydia during the previous year. The lack of a dialog about STIs or the provision of STI services at annual preventive service visits to adolescents who are sexually experienced are missed opportunities for screening and education. Comprehensive, confidential, reproductive health services, including STI screening, should be offered to all sexually experienced adolescents (Table 120-2).

Definitions, Etiology, and Clinical Manifestations
STI syndromes are generally characterized by the location of the manifestation (vaginitis) or the type of lesion (genital ulcer). Certain constellations of presenting symptoms suggest the inclusion of a possible STI in the differential diagnosis.

Urethritis
Urethritis is an STI syndrome characterized by inflammation of the urethra, usually caused by an infectious etiology. Urethritis may present with urethral discharge, dysuria, urethral irritation, or meatal pruritus. Urgency, frequency of urination, erythema of the urethral meatus, and urethral pain or burning are less common clinical presentations. Approximately 30-50% of males are asymptomatic but may have signs of discharge on diagnosis. On examination, the classic finding is mucoid or purulent discharge from the urethral meatus (Fig. 120-4). If no discharge is evident on exam, providers may attempt to express discharge by applying gentle pressure to the urethra from the base distally to the meatus 3-4 times. Chlamydia trachomatis and N. gonorrhoeae are the most commonly identified pathogens. Mycoplasma genitalium has been associated with urethritis, but data supporting Ureaplasma urealyticum have been inconsistent. Trichomonas vaginatis can cause NGU, but the prevalence varies. HSV-1, HSV-2, and Epstein-Barr virus are also potential urethritis pathogens in some cases. Sensitive diagnostic C. trachomatis and N. gonorrhoeae tests are available for the evaluation of urethritis. However, other pathogens can be considered when NGU is not responsive to treatment, although commercial diagnostic tests are not available for males. Noninfectious causes of urethritis include urethral trauma or foreign body. Unlike in females, urinary tract infections are rare in males who have no genitourinary medical history. In the typical sexually active adolescent male, dysuria and urethral discharge suggest the presence of an STI unless proven otherwise.

Epididymitis
The inflammation of the epididymis in adolescent males is most often associated with an STI, most frequently C. trachomatis or N. gonorrhoeae. The presentation of unilateral scrotal swelling and tenderness, often accompanied by a hydrocele and palpable swelling of the epididymis, associated with the history of urethral discharge, constitute the presumptive diagnosis of epididymitis. Males who practice insertive
anal intercourse are also vulnerable to *Escherichia coli* infection. Testicular torsion, a surgical emergency usually presenting with sudden onset of severe testicular pain, should be considered in the differential diagnosis (see Chapter 545). The evaluation for epididymitis should include obtaining evidence of urethral inflammation by physical exam, Gram stain of urethral secretions, urine leukocyte esterase test, or urine microscopy. A *C. trachomatis* and *N. gonorrhoeae* **nucleic acid amplification test** (NAAT) should be performed.

**Vaginitis**

Vaginitis is a superficial infection of the vaginal mucosa frequently presenting as a vaginal discharge, with or without vulvar involvement (see Chapter 549). **Bacterial vaginosis**, **vulvovaginal candidiasis**, and trichomoniasis are the predominant infections associated with vaginal discharge. Bacterial vaginosis is replacement of the normal H$_2$O$_2$–producing *Lactobacillus* sp. vaginal flora by an overgrowth of anaerobic microorganisms as well as *Gardnerella vaginalis*, *Ureaplasma*, and *Mycoplasma*. Although bacterial vaginosis is not categorized as an STI, sexual activity is associated with increased frequency of vaginosis. Vulvovaginal candidiasis, usually caused by *C. albicans*, can trigger vulvar pruritus, pain, swelling, and redness and dysuria. Findings on vaginal exam include vulvar edema, fissures, excoriations, or thick curdy vaginal discharge. Trichomoniasis is caused by the protozoan *T. vaginalis*. Infected females may present with symptoms characterized by a diffuse, malodorous, yellow-green vaginal discharge with vulvar irritation or may be diagnosed by screening an asymptomatic patient. Cervicitis can sometimes cause a vaginal discharge. Laboratory confirmation is recommended because clinical presentations may vary and patients may be infected with more than 1 pathogen.

**Cervicitis**

The inflammatory process in cervicitis involves the deeper structures in the mucous membrane of the cervix uteri. Vaginal discharge can be a manifestation of cervicitis, however, cervicitis frequently is asymptomatic. Patients also commonly present with complaints of irregular or postcoital bleeding. Two major diagnostic signs characterize cervicitis: (1) a purulent or mucopurulent endocervical exudate visible in the endocervical canal or on an endocervical swab specimen (e.g., swab sign, Fig. 120-5), commonly referred to as mucopurulent cervicitis or cervicitis, and (2) sustained endocervical bleeding easily induced by gentle passage of a cotton swab through the cervical os signifying friability. Cervical changes associated with cervicitis must be distinguished from cervical ectopy in the younger adolescent to avoid the over diagnosis of inflammation (Fig. 120-6; see Fig. 120-3). The pathogens identified most commonly with cervicitis are *C. trachomatis* and *N. gonorrhoeae*, although no pathogen is identified in the majority of cases. HSV is a less-common pathogen associated with ulcerative and necrotic lesions on the cervix.

Part XIII

Pelvic Inflammatory Disease

PID encompasses a spectrum of inflammatory disorders of the female upper genital tract, including endometritis, salpingitis, tubo-ovarian abscess, and pelvic peritonitis, usually in combination rather than as separate entities. N. gonorrhoeae and C. trachomatis predominate as the involved pathogenic organisms in younger adolescents, although PID should be approached as a multiorganism etiology, including pathogens such as anaerobes, G. vaginalis, Haemophilus influenzae, enteric Gram-negative rods, and Streptococcus agalactiae. In addition, cytomegalovirus (see Chapter 255), Mycoplasma hominis, U. urealyticum, and M. genitalium (see Chapter 224) may be associated with PID.

PID is difficult to diagnose because of the wide variation in the symptoms and signs. Many females with PID have subtle or mild symptoms resulting in many unrecognized cases. Healthcare providers should consider the possibility of PID in young sexually active females presenting with vaginal discharge and/or abdominal pain.

The clinical diagnosis of PID is based on the presence of at least 1 of the minimal criteria, either cervical motion tenderness, uterine tenderness, or adnexal tenderness, to increase the diagnostic sensitivity and reduce the likelihood of missed or delayed diagnosis. Providers should also consider that adolescents are the population in which PID is typically diagnosed and thus should have a low threshold for initiating empiric treatment. In addition, the majority of females with PID have either mucopurulent cervical discharge or evidence of white blood cell (WBC) on a microscopic evaluation of a vaginal fluid saline preparation. If the cervical discharge appears normal and no WBCs are observed on the wet prep of vaginal fluid, the diagnosis of PID is unlikely, and alternative causes of pain should be investigated. Specific, but not always practical, criteria for PID include evidence of endometritis on biopsy, transvaginal sonography or MRI evidence of thickened, fluid-filled tubes, or Doppler evidence of tubal hyperemia or laparoscopic evidence of PID.

Genital Ulcer Syndromes

An ulcerative lesion in a mucosal area exposed to sexual contact is the unifying characteristic of infections associated with these syndromes. These lesions are most frequently seen on the penis and vulva, but also occur on oral and rectal mucosa depending on the adolescent’s sexual practices. HSV and Treponema pallidum (syphilis) are the most common organisms associated with genital ulcer syndromes.

Genital herpes, the most common ulcerative STI among adolescents, is a chronic, lifelong viral infection. Two sexually transmitted HSV types have been identified, HSV-1 and HSV-2. The majority of cases of recurrent genital herpes are caused by HSV-2. However, among young women and men who have sex with men, an increasing proportion of anogenital herpes has been HSV-1. Most HSV-2–infected persons are unaware of their diagnosis because they experience mild or unrecognized infections but continue to shed virus intermittently in the genital tract. Therefore, the majority of genital herpes infections are transmitted by asymptomatic persons who are unaware of their infection.

Although the initial herpetic lesion is a vesicle, by the time the patient presents clinically, the vesicle most often has ruptured spontaneously, leaving a shallow, painful ulcer (Fig. 120-7A) although recurrences are generally less intense and painful (Fig. 120-7B). Up to 50% of first genital herpes episodes are caused by HSV-1, but recurrences and subclinical shedding are much more frequent for genital HSV-2 infection.

Syphilis is a less common cause of genital ulcers in adolescents than in adults. Lymphogranuloma venereum caused by C. trachomatis serovars L1-L3 is uncommon, although outbreaks do occur in men who have sex with men (MSM). In these circumstances, proctitis or protococitis is the usual manifestation. HIV is often present in affected men. Unusual infectious causes of genital, anal, or perianal ulcers in the United States and other industrialized countries include chancroid and donovanosis.

Clinical characteristics differentiating the lesions of the most common infections associated with genital ulcers are presented in Table 120-3, along with the required laboratory diagnosis to identify the causative agent accurately. The differential diagnosis includes Behçet disease (see Chapter 161), Crohn disease (see Chapter 336), aphthous ulceration, and acute genital ulcers caused by cytomegalovirus (see Chapter 255) or Epstein-Barr virus (see Chapter 254). Acute genital ulcers often follow a flu or mononucleosis-like illness in an immunocompetent female and is unrelated to sexual activity. The lesions are 0.5–2.5 cm in size, bilateral, symmetric, multiple, painful, and necrotic, and are associated with inguinal lymphadenopathy. This primary infection is also associated with fever and malaise. The diagnosis may require Epstein-Barr virus titers, or polymerase chain reaction (PCR) testing. Treatment is supportive care including pain management.

Genital Lesions and Ectoparasites

Lesions that present as outgrowths on the surface of the epithelium and other limited epidermal lesions are included under this categorization of syndromes. HPV can cause genital warts and genital cervical abnormalities that can lead to cancer. Genital HPV types are classified according to their association with cervical cancer. Infections with low-risk types, such as HPV types 6 and 11, can cause benign or low-grade changes in cells of the cervix, genital warts, and recurrent
HIV Disease and Hepatitis B
HIV and hepatitis B present as an asymptomatic, unexpected occurrences in most infected adolescents. High vaccination coverage rates among infants and adolescents have resulted in substantial declines in acute hepatitis B incidence among U.S.-born adolescents. Risk factors identified in the history or routine screening during prenatal care are much more likely to result in suspicion of infection, leading to the appropriate laboratory screening, than are clinical manifestations in this age group (see Chapters 276 and 358).

respiratory papillomatosis. High-risk HPV types can cause cervical, anal, vulvar, vaginal, and head and neck cancers. High-risk HPV types 16 and 18 are detected in approximately 70% of cervical cancers. Persistent infection increases the risk of cervical cancer. Molluscum contagiosum and condyloma lata associated with secondary syphilis complete the classification of genital lesion syndromes. As a result of the close physical contact during sexual contact, common ectoparasitic infestations of the pubic area occur as pediculosis pubis or the papular lesions of scabies (see Chapter 668).
**Diagnosis**

Most commonly, adolescents infected with viral and bacterial STI pathogens do not report symptoms suggestive of infection. With the increased use of very sensitive, noninvasive chlamydia and gonorrhea NAATs, providers are finding that most genital infections in females as well as many males are asymptomatic. A thorough sexual history is key to identifying adolescents who should be screened for STIs and for identifying those who require a laboratory diagnostic evaluation for a sexually transmitted disease syndrome.

When eliciting a sexual history, discussions should be appropriate for the patient’s development level. In addition to questions regarding vaginal or urethral discharge, genital lesions, and lower abdominal pain among females, one should ask about prior treatment of any STI symptoms, including self-treatment using nonprescription medications. Dyspareunia is a consistent symptom in adolescents with PID. Providers must ask about oral or anal sexual activity to determine sites for specimen collection.

**Urethritis** should be objectively documented by evidence of inflammation or infectious etiology. Patient complaint without objective clinical or laboratory evidence does not fulfill diagnostic criteria. Inflammation can be documented by (a) observing urethral mucopurulent discharge, (b) ≥2 WBC per high-power field on microscopic examination Gram stain urethral secretions, (c) urine microscopic findings of ≥10 WBCs per high power field of first-void urine specimen, or (d) a positive urine leucocyte esterase test of a (first-void urine) specimen. Laboratory evaluation is essential to identify the involved pathogens to determine treatment, partner notification, and disease control. *C. trachomatis* and *N. gonorrhoeae* NAATs of a urine specimen are recommended. The presence of Gram-negative intracellular diplococci on microscopy obtained from a male urethral specimen confirms the diagnosis of gonococcal urethritis.

An essential component of the diagnostic evaluation of vaginal, cervical or urethral discharge is a chlamydia and gonorrhea NAAT. NAATs are the most sensitive chlamydia and gonorrhea tests available and are licensed for use with urine, urethral, vaginal, and cervical specimens. Many of the chlamydia NAATs are approved by the Food and Drug Administration (FDA) to test patient-collected vaginal swabs in the clinical setting and liquid cytology specimens. Female vaginal swab specimens and male first-void urine are considered the optimal specimen types. Female urine remains an acceptable chlamydia and gonorrhea NAAT specimen, but may have slightly reduced performance when compared with cervical or vaginal swab specimens. Urine is the recommended specimen for male urethral infection. Gonorrhea and chlamydia NAATs perform well on rectal and oropharyngeal specimens and can be performed by clinical laboratories that have completed the appropriate verification studies to obtain Clinical Laboratory Improvement Amendments (CLIA)-approval, which include most commercial laboratories.

Evaluation of adolescent females with vaginitis includes laboratory data. Traditionally, the cause of vaginal symptoms was determined by pH and microscopic examination of the discharge. However, newer CLIA-waived point-of-care vaginitis tests are available. Using pH paper, an elevated pH (i.e., >4.5) is common with bacterial vaginosis or trichomoniasis. For microscopic exam, a slide can be made with the discharge diluted in 1-2 drops of 0.9% normal saline solution and another slide with discharge diluted in 10% potassium hydroxide (KOH) solution. Examining the saline specimen slide under a microscope may reveal motile or dead *T. vaginalis* or *clue cells* (epithelial cells with borders obscured by small bacteria), which are characteristic of bacterial vaginosis. WBCs without evidence of trichomonads or yeast are usually suggestive of cervicitis. The yeast or pseudohyphae of *Candida* species are more easily identified in the KOH specimen (Fig. 120-8). The

![Figure 120-8](image_url) Common normal and abnormal microscopic findings during examination of vaginal fluid. KOH, potassium hydroxide solution; PMN, polymorphonuclear leukocyte; RBC, red blood cell. *(From Adolescent medicine: state of the art reviews, vol 14, no 2, Philadelphia, 2003, Hanley & Belfus, pp 350–351.)*
sensitivity of microscopy is approximately 50% and requires immediate evaluation of the slide for optimal results. Therefore, lack of findings does not eliminate the possibility of infection. More sensitive, point-of-care vaginitis tests include the OSOM Trichomonas Rapid Test (Sekisui Diagnostics, Lexington, MA), an immunochromatographic capillary flow dipstick technology that reports an 83% sensitivity; and the OSOM BVBLUE Test (Sekisui Diagnostics, Lexington, MA), which detects elevated vaginal fluid sialidase activity, an enzyme produced by bacterial pathogens associated with bacterial vaginosis including Gardnerella, Bacteroides, Prevotella, and Mobiluncus, that reports a 90% sensitivity. Both of these tests are CLIA-waived with results are available within 10 minutes.

Clinical laboratory-based vaginitis tests are also available. The Affirm VPIII (Becton Dickenson, San Jose, CA), a nucleic acid probe test that evaluates for T. vaginalis, G. vaginalis, and C. albicans, is a moderate complexity laboratory test, has a sensitivity >83% and a specificity >97%, with results are available within 45 min. Some gonorrhea and chlamydia NAATs also offer an assay for T. vaginalis testing of female specimens tested for N. gonorrhoeae and C. trachomatis, which are considered the gold standard for trichomonas testing.

Objective signs of vulvar inflammation in the absence of vaginal pathogens, along with a minimal amount of discharge, suggest the possibility of mechanical, chemical, allergic, or other noninfectious irritation of the vulva (Table 120-4).

The definitive diagnosis of PID is difficult based on clinical findings alone. Clinical diagnosis is imprecise and no single historical, physical, or laboratory finding is both sensitive and specific for the diagnosis of acute PID. Clinical criteria have a positive predictive value of only 65-90% compared with laparoscopy. Although healthcare providers should maintain a low threshold for the diagnosis of PID, additional criteria to enhance specificity of diagnosis, such as transvaginal ultrasonography, can be considered (Table 120-5).

Cell culture and PCR are the preferred HSV tests. Viral culture sensitivity is low and false negatives do occur as a consequence of intermittent viral shedding. NAATs, including PCR assays for HSV DNA, are more sensitive and increasingly available for diagnosing intermittent viral shedding. NAATs, including PCR assays for HSV DNA, are more sensitive and increasingly available for diagnosing genital HSV. The Tzanck test is insensitive and nonspecific and should not be relied on.

Accurate type-specific HSV serologic assays are based on the HSV-specific glycoprotein G2 (HSV-2) and glycoprotein G1 (HSV-1). Both laboratory-based and point-of-care tests are available. Because nearly all HSV-2 infections are sexually acquired, the presence of type-specific HSV-2 antibody implies anogenital infection. The presence of HSV-1 antibody alone is more difficult to interpret because of the frequency of oral HSV infection acquired during childhood. Type-specific HSV serologic assays might be useful in the following scenarios: (1) recurrent genital symptoms or atypical symptoms with negative HSV cultures; (2) a clinical diagnosis of genital herpes without laboratory confirmation; and (3) a patient with a partner with genital herpes, especially if considering suppressive antiviral therapy to prevent transmission.

For syphilis testing, nontreponemal tests, such as the rapid plasma reagin (RPR) or Venereal Disease Research Laboratory (VDRL), and treponemal testing, such as fluorescent treponemal antibody absorbed tests, the T. pallidum passive particle agglutination (TP-PA) assay, various enzyme and chemiluminescence immunoassays (EIA/CIA) are recommended. However, many clinical laboratories have adopted a reverse sequence of screening in which a treponemal EIA/CIA is performed first, followed by testing of reactive sera with a nontreponemal test (e.g., RPR). A positive treponemal EIA or CIA test can identify both previously treated and untreated or incompletely treated syphilis. False-positive results can occur, particularly among populations with low syphilis prevalence. Persons with a positive treponemal screening test should have a standard nontreponemal test with titer, such as an RPR or VDRL to guide patient management decisions. If EIA/CIA and nontreponemal test (e.g., RPR or VDRL) test results are discordant, the laboratory should perform a different treponemal test to confirm the results of the initial test. Patients with discordant serologic results by EIA/CIA and RPR/VDRL testing whose sera reactive by TP-PA testing are considered to have past or present syphilis; if sera is TP-PA nonreactive, syphilis is unlikely (Fig. 120-9).

| **Table 120-5 Evaluation for Pelvic Inflammatory Disease**

#### 2014 CENTERS FOR DISEASE CONTROL AND PREVENTION DIAGNOSTIC CRITERIA

**Minimal Criteria**
- Cervical motion tenderness
- or
- Uterine tenderness
- or
- Adnexal tenderness

**Additional Criteria to Enhance Specificity of the Minimal Criteria**
- Oral temperature >38.3°C (>101°F)
- Abnormal cervical or vaginal mucopurulent discharge*
- Presence of abundant numbers of white blood cells on saline microscopy of vaginal secretions*
- Elevated ESR or C-reactive protein
- Laboratory documentation of cervical Neisseria gonorrhoeae or Chlamydia trachomatis infection

**Most Specific Criteria to Enhance the Specificity of the Minimal Criteria**
- Transvaginal sonography or MRI techniques showing thickened, fluid-filled tubes, with or without free pelvic fluid or tuboovarian complex, or Doppler studies suggesting pelvic infection (e.g., tubal hyperemia)
- Endometrial biopsy with histopathologic evidence of endometritis
- Laparoscopic abnormalities consistent with PID
- Differential Diagnosis (Partial List)
  - GI: appendicitis, constipation, diverticulitis, gastroenteritis, inflammatory bowel disease, irritable bowel syndrome
  - GYN: ovarian cyst (intact, ruptured, or torsed), endometriosis, dysmenorrhea, ectopic pregnancy, mitelschmerz, ruptured follicle, septic or threatened abortion, tuboovarian abscess
  - Urinary tract: cystitis, pyelonephritis, urethritis, nephrolithiasis

*If the cervical discharge appears normal and no WBCs are observed on the wet prep of vaginal fluid, the diagnosis of PID is unlikely and alternative causes of pain should be investigated.

HIV screening should be discussed and offered in healthcare settings to all adolescents >15 yr and to younger adolescents with HIV risk factors. Rapid HIV testing with the availability of results in 10-20 min can be useful in settings in which the likelihood of adolescents returning for their results is low. Point-of-care, CLIA-waived tests for whole blood fingerstick and oral fluid specimen testing are available. Clinical studies have demonstrated that the rapid HIV test performance is comparable to those of EIAs. Because some reactive test results may be false-positive, every reactive rapid test must be confirmed.

**Treatment**

See Part XVII for chapters on the treatment of specific microorganisms and *Table 120-6 to 120-8*. Treatment regimens using nonprescription products for candida vaginitis and pediculosis reduce financial and access barriers to rapid treatment for adolescents, but there are potential risks for inappropriate self-treatment and complications from untreated more serious infections that must be considered before using this approach. Minimizing noncompliance with treatment, finding and treating the sexual partners, addressing prevention and contraceptive issues, offering available vaccines to prevent STIs and making every effort to preserve fertility are additional physician responsibilities.

Chlamydia and gonorrhea-infected males and females should be retested approximately 3 mo after treatment, regardless of whether they believe that their sex partners were treated or whenever persons next present for medical care in the 12 mo following initial treatment. Once an infection is diagnosed, partner evaluation, testing, and treatment are recommended for sexual contacts within 60 days of symptoms or diagnosis or the most recent partner if sexual contact was >60 days, even if the partner is asymptomatic. Abstinence is recommended for at least 7 days after both patient and partner are treated. A test for pregnancy should be performed for all females with suspected PID as the test outcome will affect management. Repeat testing 3 mo after treatment is recommended for *Trichomonas* infection.

Diagnosis and therapy are often necessarily carried out within the context of a confidential relationship between the physician and the patient. Therefore, the need to report certain STIs to health department authorities should be clarified at the outset. Health departments are HIPAA-exempt and will not violate confidentiality. The health department's role is to assure that treatment and case finding have been minimized and the infectious partner's role is to assure that treatment and case finding have been accomplished and that sexual partners have been notified of their STI exposure. Expedited partner therapy (EPT), where the patient, preferably, delivers the medication, or a prescription for the medication if medication itself is not possible to the partner for treatment without a

Clinical assessment, is a strategy to reduce further transmission of infection, particularly for male partners of women with gonorrhea and/or chlamydia who are otherwise unlikely to seek care for STI exposure. In randomized trials, EPT has reduced the rates of persistent or recurrent gonorrhea and chlamydia infection. Serious adverse reactions are rare with recommended chlamydia and gonorrhea treatment regimens, such as doxycycline, azithromycin, and ceftriaxime. Transient gastrointestinal side effects are more common but rarely result in severe morbidity. Many states expressly permit EPT or may potentially allow its practice. Resources for information regarding EPT and state laws are available at the Centers for Disease Control and Prevention website ([http://www.cdc.gov/std/ept/](http://www.cdc.gov/std/ept/)).

**Prevention**

Healthcare providers should integrate sexuality education into clinical practice with children from early childhood through adolescence. Providers should counsel adolescents regarding sexual behaviors associated with risk of STI acquisition and should educate using evidence-based prevention strategies, which include a discussion of abstinence and other risk reduction strategies, such as consistent and correct condom use. The U.S. Preventative Task Force recommends high-intensity behavioral counseling to prevent STIs for all sexually active adolescents. The HPV vaccine, either bivalent or quadrivalent, is recommended for 11 and 12 yr old female routine immunization. Catch-up vaccination is recommended for females age 13-26 yr who...

have not yet received or completed the vaccine series. The routine use of quadrivalent HPV vaccine is recommended in males age 11 or 12 yr. The CDC’s Advisory Committee on Immunization Practices also recommends vaccination with quadrivalent HPV vaccine for males age 13 through 21 yr who have not yet received or completed the vaccine series; males age 22 through 26 yr may be vaccinated.

* Bibliography is available at Expert Consult.  

Chronic fatigue syndrome (CFS) describes a complex, diverse, and debilitating illness characterized by chronic or intermittent fatigue accompanied by selected symptoms of $\geq 3$ mo (young children) or $\geq 6$ mo duration (adolescents or adults). The combination of fatigue and symptoms interferes significantly with usual daily activities and has no apparent medical explanation. The fatigue does not require exertion by the patient, nor does rest relieve it. Post-exertion malaise (i.e., worsening of fatigue and sickness symptoms after mental or physical exertion lasting more than 24 hr) is considered by some to be characteristic of CFS. A definitive causal agent or process has not been identified, although the differential diagnosis includes many infectious and inflammatory diseases. The understanding of this condition is largely from studies among adults and adolescents, with limited descriptions of chronic fatigue illness among younger children.

This illness was formally defined in 1988 as *chronic fatigue syndrome* because persistent and unexplained fatigue was considered the principal and invariable physical symptom. A variety of names have been used to describe the syndrome (chronic mononucleosis, chronic Epstein-Barr virus infection, myalgic encephalomyelitis, post-infection syndrome, immune dysfunction syndrome), and several case definitions are in use in both clinical and research settings. Some of the more widely used definitions are the 1994 International Research Case Definition (an update of the 1988 version), the Oxford (UK) Guidelines for research, the Myalgic Encephalomyelitis/Chronic Fatigue Syndrome: Clinical working case definition, diagnostic and treatments protocols, also commonly referred to as the Canadian Consensus Criteria for CFS/ME (2003), and the 2011 International Consensus Criteria for Myalgic Encephalomyelitis (ME). In 2006, the International Association of Chronic Fatigue Syndrome Pediatric Case Definition Working group developed a case definition specifically for children and adolescents with ME/CFS, utilizing the 3-mo duration of fatigue. In the UK, pediatric practitioners adhere to guidelines in the National Institute for Health and Clinical Excellence (NICE); Chronic fatigue syndrome/Myalgic encephalomyelitis (or encephalopathy); Diagnosis and Management (2007), which includes the 3-mo duration criterion.

The Institute of Medicine (IOM) of the National Academy of Science was commissioned by the Department of Health and Human Services (HHS) to conduct a study to evaluate existing diagnostic criteria and to develop evidence-based diagnostic criteria for use by clinicians. Their recommendations were published in February 2015. The IOM case definition is intended to apply to all ages, and the report includes a special focus on pediatrics. The IOM suggested new diagnostic criteria and a new name, *systemic exertion intolerance disease*, in part to emphasize the post-exertion malaise criterion and bring greater understanding about the illness.

**Epidemiology**

Between 0.2% and 2.3% of children or adolescents suffer from CFS based on worldwide studies. Most epidemiology studies utilize the 1994 definition. CFS is more prevalent in adolescents than in younger children. The large variation in the CFS prevalence estimates may be
due to variation in study methodology, such as the study population composition (special clinic versus general practice or general population) and data collection procedures (parent/self-reporting vs. clinical evaluation; the choice of case definition and method of applying case definition). Sex/gender distribution differs from that in adults with a more equal distribution in children less than 15 yr of age, while remaining 2- to 3-fold higher in females ages 15-18 yr. Few studies have reported the incidence of CFS among children <10 yr of age, leading to uncertainty in this age group. In adolescents in the Netherlands, the pediatrician-diagnosed incidence of CFS/ME was reported to be 0.01%, while in the UK the incidence was 0.5%.

**PATHOGENESIS**

Although the cause of CFS is unknown, some patients correlate the onset with a recent episode of a viruslike illness such as infectious mononucleosis (10-12%) (see Chapter 254). A potentially pathophysiologic relationship of CFS to infection is suggested because the sickness or illness behaviors elicited by the nonspecific or innate host responses in infections in general are present in CFS. CFS-like illness after infectious mononucleosis is not predicted by viremia or an altered host response to Epstein-Barr virus infection, but is associated with the severity of the primary infection. There have been a wide variety of other candidate infections associated with postinfection fatigue syndromes, particularly in adults or teenagers older than 16 yr. Efforts continue to determine if infections with these or other agents may produce the illness.

Similarities between CFS symptoms and those experienced by patients with autoimmune and other inflammatory disorders raises the issue of primary perturbations in the immune system in the pathogenesis of CFS. Immunologic alterations (hypogammaglobulinemia or hypergammaglobulinemia, immunoglobulin subclass deficiencies, elevated levels of circulating immune complexes, mild increased helper/suppressor lymphocyte ratios, natural killer cell dysfunction, and monocyte dysfunction) have been reported in adult patients with CFS. These findings have not been consistent among studies. While CFS patients as a group appear to differ from healthy controls, in most studies the laboratory values of the immune parameters are not outside the normal range.

Autonomic nervous system changes are suggested by the orthostatic intolerance experienced by some CFS patients. Orthostatic intolerance (OI) syndromes with circulatory dysfunction including neurally mediated hypotension, instantaneous orthostatic hypotension, and postural tachycardia syndrome have been observed in some patients with CFS and could contribute to the syndrome. The pathophysiology of these manifestations among adolescents with CFS is unclear, but in postinfection states, they could be associated with failure to replenish mineral and fluid losses that accompany infections or to immune-mediated injury (auto-antibodies directed against the autonomic nervous system).

Because the widespread musculoskeletal pain in CFS is similar to that in fibromyalgia (Chapter 168.3), and fibromyalgia and CFS are often considered overlapping syndromes, they may share similarities in pathogenesis. Fibromyalgia pain is thought to be due to neurochemical imbalances in the central nervous system. Neurochemical changes represent another area for research into the origins of development and persistence of CFS.

A variety of other hypotheses for the biologic basis of this illness are being investigated. These include alterations in energy metabolism (particularly as related to exercise and post-exertion malaise), in sleep, as well as in stress response and the hypothalamic-pituitary-axis. Understanding CFS has proved so challenging because it represents more than one underlying pathophysiology. Current studies are attempting to stratify or subgroup patients to address this possibility.

**CLINICAL MANIFESTATIONS**

The dominant symptoms expressed by adolescents are similar to those observed in adults and include fatigue and an increased level of illness after physical or mental activity. In younger children, who frequently do not spontaneously describe symptoms, exertion induces behavioral changes manifested by a lack of their usual energy. In adolescents, the fatigue and post-exertional malaise may lead to reduced participation in school activities and time spent with friends. Cognitive problems and difficulties in concentrating are common and are indicated by a decreased ability to keep up with homework and a drop in grades. Sleep complaints include difficulty falling or staying asleep, daytime sleepiness, frequent awakening, and intense and vivid dreaming.

While nonrestorative nighttime sleeping is common, diagnosed sleep disorders, such as restless legs or sleep apnea, are not. Myalgias and arthralgias may accompany fatigue and altered sleep. Sore throat and lymph node tenderness occur in some children but may be part of an inciting illness. Adolescents also have increased complaints of headaches, abdominal pain, nausea, and hypersensitivity to touch and noise.

Patients diagnosed with CFS in primary care practices are more likely to report an abrupt onset to their symptoms, often as part of an initial virus-like illness, whereas gradual onset is more common in those identified in population-based studies. School absenteeism is a major problem. In one study two thirds of adolescents missed >2 wk of school over a 6-week observation period and one third required a home tutor. Unlike school phobia, inactivity due to CFS persists on the weekends and during holidays as it does during the school week.

Although fatigue and accompanying symptoms are subjective, the magnitude of impairment of each component can be measured by questionnaires addressing pain and function or, in the case of suspected orthostatic instability, by recording routine or supine/standing heart rate and blood pressure. Fatigue should not be dismissed as a minor ailment. It is generally manifested as lassitude, profound tiredness, intolerance of exertion with easy fatigability, and general malaise.

Abnormal physical examination findings are conspicuously absent, providing reassurance and consternation to both the patient and the physician. The presence of unusual symptoms such as chest palpitations, visual blurring, paresthesias, dry eyes and mouth, diarrhea, cough, night sweats, and rash) should suggest a diagnosis other than CFS. Weight loss, as seen in chronic infections or inflammatory conditions, is uncommon in CFS.

**DIAGNOSIS**

There are no pathognomonic signs or diagnostic tests for CFS. The diagnosis is clinically defined based on inclusion and exclusion criteria (Fig. 121-1). The diagnostic criteria are applicable to adults and adolescents >11 yr of age because of the current requirement for a self-generated history. The 3- or 6-mo criterion in CFS case definitions does not mean that evaluation and symptom management should wait until that criterion is met before intervention can begin.

CFS is difficult to diagnose in children, who have trouble describing their symptoms and articulating their concerns. Sole reliance on parental history for diagnosis is fraught with confusion because of the inaccuracy of the historical information. A combination of child and parent reports is most effective. It is important to document the child’s activity levels and worsening symptoms after physical or mental endeavors. Changes in participation in hobbies and social activities can help identify illness effects on daily activities.

The diagnosis of CFS can be established only after alternative medical and psychiatric causes of fatigue and illness, many of which are treatable, have been excluded. These include any medical condition that may explain the presence of a chronic illness, such as untreated hypothyroidism, respiratory and/or food allergies, sleep apnea, narcolepsy, drug abuse, an adverse effect of medication, or severe obesity. A previously diagnosed medical condition with uncertain resolution that may explain chronic fatigue should be clarified, such as unresolved cases of hepatitis B or C virus infection.

Certain illnesses, for example, fibromyalgia and depression, share similar symptoms with CFS, but are not exclusionary diagnoses. They should be considered in the differential diagnosis in selected cases. There is concern that CFS might be mistaken for readily identifiable psychiatric disorders, but evidence supports differences in clinical

---

Presentation between CFS and mood/anxiety disorders. CFS should not be diagnosed in persons with prior diagnoses of a major depressive disorder with psychotic or melancholic features, bipolar affective disorders, schizophrenia of any subtype, delusional disorders of any subtype, dementias of any subtype, anorexia nervosa, bulimia nervosa, or alcohol or other substance abuse within 2 yr before the onset of the chronic fatigue or at any time afterward.

Although evaluation of each patient should be individualized, initial laboratory evaluation should be limited to screening laboratory tests to provide reassurance of the lack of significant medical illnesses (see Fig. 121-1). Further tests should be directed primarily toward excluding treatable diseases that may be suggested by the symptoms or physical findings that are present in specific patients.

**MANAGEMENT**

Management of CFS is based on relief of the core and most disruptive symptoms in the individual patient (Fig. 121-1). The diagnostic criterion of 3-6 mo duration of illness should not delay evaluation and symptom management, as these may be initiated as soon as the child or adolescent presents with a CFS-like picture. Problems with sleep can be addressed by encouraging patients to adopt good sleep habits using standard sleep hygiene techniques. It may be beneficial to refer the patient to a specialist for identification and treatment of sleep disorders and disturbances. Once pain is found not to be related to specific diseases or illnesses, it is best addressed through nonpharmacologic treatment (see Chapter 62).

One of the nonpharmacologic approaches to pain management, cognitive behavioral therapy (CBT), may also assist patients in coping with CFS. Through explanation and changes in perception of the origins of the illness, CBT may help patients and their families develop coping skills and provide emotional support. Improved methods of coping may allow some improved function while living with the illness. Comorbid psychiatric disorders require appropriate intervention.

While the overall goal is to help CFS patients tolerate activity, children with CFS should avoid physical or mental efforts that result in aggravated CFS symptoms. Return to school should be initiated gradually but systematically to resume normal attendance. Home tutoring may be an interim alternative. Parents can work with teachers and administrators to redefine expectations of activity and performance for children with CFS. Because of the crucial importance of learning socialization skills during childhood and adolescence, even brief periods of attendance during lunch or favorite after-school activities should be encouraged. Complete bed rest and physical inactivity perpetuates immobility and leads to deconditioning. Activities benefit children with certain chronic illnesses in ways other than overcoming deconditioning; however, rapid remobilization usually exacerbates symptoms and should be avoided.

Continued empathy and support by the treating physician are important in maintaining a physician-patient relationship conducive to managing this illness. Careful attention must be directed to the family dynamics to identify and resolve family problems or psychopathology that may be contributing to a child’s perceptions of his or her
symptoms. Periodic medical reevaluation is warranted for early detection of other identifiable causes of chronic fatigue and other symptoms, especially with interval development of new symptoms. No data suggest relief of symptoms or cure of CFS by dietary or vitamin supplements.

**PROGNOSIS**

The clinical course of CFS is highly variable and patients should be informed that their symptoms will likely wax and wane. Children and adolescents with CFS appear to have a more optimistic outcome than adults, typically with an undulating course of gradual but substantial symptomatic improvement, or full recovery, 1-4 yr after diagnosis. Overall, a good functional outcome has been reported in up to 80% of cases. Poor prognostic factors include a gradual onset, increasing school absenteeism, lower socioeconomic status, chronic maternal health problems, and untreated comorbid individual or family psychiatric disorders. Favorable prognostic factors include patient control of their individual rehabilitation program with continued support from health professionals and family members and improvement in orthostatic factors.

*Bibliography is available at Expert Consult.*
Recurrent infections or fevers in children are among the most frequent clinical dilemmas for primary care physicians. A major reason for the apparent high rate of recurrent infections in children is repeated exposure to common and usually benign infectious agents in childcare and other group settings.

Primary care physicians must have a high index of suspicion if defects of the immune system are to be diagnosed early enough that appropriate treatment can be instituted before irreversible damage develops. Diagnosis is difficult because, until recently, primary immunodeficiency diseases have not been screened for at any time during life anywhere in the world, and most affected do not have abnormal physical features. Screening for severe combined immunodeficiency (SCID; T-cell lymphopenia) is part of the newborn screening programs in 21 states of the United States now; the hope is that it will eventually be performed nationwide. There is also a beginning effort to do this in Europe. Extensive use of antibiotics may mask the classic presentation of many primary immunodeficiency diseases. Evaluation of immune function should be initiated in those rare infants or children who do have clinical manifestations of a specific immune disorder and in all who have a positive family history of early infant death or a known immunodeficiency disorder, unusual, chronic, or recurrent infections such as (1) 1 or more serious bacterial infections (sepsis, meningitis); (2) 2 or more serious respiratory or documented bacterial infections (cellulitis, abscesses, draining otitis media, pneumonia, lymphadenitis) within 1 yr; (3) serious infections occurring at unusual sites (liver, brain abscess); (4) infections with unusual pathogens (Pneumocystis jiroveci, Aspergillus, Serratia marcescens, Nocardia, Burkholderia cepacia); and (5) infections with common childhood pathogens but of unusual severity (Table 122-1). Additional clues to immunodeficiency include failure to thrive with or without chronic diarrhea, persistent infections after receiving live vaccines, and chronic oral or cutaneous moniliasis. Tables 122-2 and 122-3 note certain clinical features that are suggestive of immunodeficiency syndromes.

Children with defects in antibody production, phagocytic cells, or complement proteins have recurrent infections with encapsulated bacteria and may grow and develop normally despite their recurring infections, unless they develop bronchiectasis from repeated lower respiratory tract bacterial infections or persistent enteroviral infections of the central nervous system. Patients with only repeated benign viral infections (with the exception of persistent enterovirus infections) are not as likely to have an immunodeficiency. By contrast, patients with deficiencies in T-cell function usually develop opportunistic infections or serious illnesses from common viral agents early in life, and they fail to thrive (Table 122-4).

The initial evaluation of immunocompetence includes a thorough history, physical examination, and family history (Table 122-5). Most immunologic defects can be excluded at minimal cost with the proper choice of screening tests, which should be broadly informative, reliable, and cost-effective (Table 122-6 and Fig. 122-1). A complete blood count (CBC), manual differential count, and erythrocyte sedimentation rate are among the most cost-effective screening tests. If the erythrocyte sedimentation rate is normal, chronic bacterial or fungal infection is unlikely. If an infant's neutrophil count is persistently elevated in the absence of any signs of infection, a leukocyte adhesion deficiency should be suspected. If the absolute neutrophil count is normal, congenital and acquired neutropenias and leukocyte adhesion defects are excluded. If the absolute lymphocyte count is normal, the patient is not likely to have a severe T-cell defect, because T cells normally constitute 70% of circulating lymphocytes and their absence results in striking lymphopenia. Normal lymphocyte counts are higher in infancy and early childhood than later in life (Fig. 122-2). Knowledge of normal values for absolute lymphocyte counts at various ages in infancy and childhood is crucial in the detection of T-cell defects. At 9 mo of age, an age when infants affected with severe T-cell immunodeficiency are likely to present, the lower limit of normal is 4,500 lymphocytes/mm³. Absence of Howell-Jolly bodies or pitted erythrocytes by microscopic examination of erythrocytes rules against congenital asplenia. Normal platelet size or count excludes Wiskott-Aldrich syndrome. If newborn screening for T-cell lymphopenia were to be performed on all infants, SCID could be detected at birth, and lifesaving immunologic reconstitution could then be provided to all affected infants shortly after birth and before they become infected.

Patients found to have abnormalities on any screening tests should be characterized as fully as possible before any type of immunologic treatment is begun, unless there is a life-threatening illness (Table 122-7). Some “abnormalities” may prove to be laboratory artifacts and, conversely, an apparently straightforward diagnosis may prove to be a much more complex disorder. For patients with recurrent or unusual bacterial infections, evaluation of T-cell and phagocytic cell functions is indicated even if results of initial screening tests including the CBC and manual differential, immunoglobulin levels, and CH₅₀ are normal.

Because of the lack of screening, the true incidence and prevalence of primary immunodeficiency diseases are unknown, although the incidence has been estimated to be 1:10,000 births (Table 122-8). If true, this is higher than some disorders that are part of the newborn metabolic screening program (phenylketonuria is 1:16,000) (see Chapter 85.1). Approximately 80% of the mutated genes causing the more than 220 known primary immunodeficiency diseases have been identified. This is information crucial for genetic counseling and that could eventually be used in neonatal screening. Newborn or early childhood screening would be extremely valuable so that timely initiation of appropriate therapy can be initiated before infections develop; it is likely that many affected patients die before a diagnosis is determined.

**B CELLS**

Antibody production by B cells is easily evaluated by measuring serum immunoglobulin levels and determining antibody titers to protein and polysaccharide antigens.

A simple screening test for B-cell defects is the measurement of serum immunoglobulin (Ig) A. If the IgA level is normal, selective IgA

One useful test for B-cell function is to determine the presence and titer of isohemagglutinins, or natural antibodies to type A and B red blood cell polysaccharide antigens. This test measures predominantly IgM antibodies. Isohemagglutinins may be absent normally in the 1st 2 yr of life and are always absent if the patient is blood type AB.

Because most infants and children are immunized with diphtheria-tetanus-pertussis, conjugated *Haemophilus influenzae* type b, and pneumococcal conjugate vaccine, it is often informative to test for specific antibodies to diphtheria, tetanus, *H. influenzae* polyribosyl phosphate, and pneumococcal antigens. If the titer is low, measurement of antibodies to diphtheria or tetanus toxoids before and 2 wk after a pediatric diphtheria-tetanus-pertussis or diphtheria-tetanus booster is helpful in assessing the capacity to form IgG antibodies to protein antigens. To evaluate a patient’s ability to respond to IgA deficiency, which is the most common B-cell defect, is excluded, as are most of the permanent types of hypogammaglobulinemia, as IgA is usually very low or absent in those conditions. If IgA is low, IgG and IgM should also be measured. Patients who are receiving corticosteroids or who have protein-losing states (nephrosis, protein-losing enteropathy) often have low serum IgG concentrations but produce antibodies normally. Thus, if immunoglobulins are low, it is crucial before starting intravenous immunoglobulin therapy to assess the patient’s ability to respond to protein antigens. To evaluate a patient’s ability to respond to
polysaccharide antigens, anti-pneumococcal antibodies can be measured before and 3 wk after immunization with 23 valent unconjugated pneumococcal polysaccharide vaccine in patients 2-3 yr old or older. Antibodies detected in these tests are of the IgG isotype. These antibody studies can be performed in several different laboratories, but it is important to choose a reliable laboratory and to use the same laboratory for preimmunization and postimmunization titters. In children older than 2 yr of age with low anti-pneumococcal antibody titers after pneumococcal polysaccharide vaccine immunization, it is useful to boost with conjugate pneumococcal vaccine twice, 1 mo apart, before giving a polysaccharide pneumococcal vaccine 1 mo later and then measuring antibody titers 3 wk later. Patients with significant or permanent B-cell defects do not produce either IgM or IgG antibodies normally. If results of these tests prove to be normal and the immunoglobulins remain low, studies should be performed to evaluate the possible loss of immunoglobulins through the urinary or gastrointestinal tracts (nephrotic syndrome, protein-losing enteropathies, intesti-nal lymphangiectasia). Very high serum concentrations of 1 or more immunoglobulin classes suggest HIV infection, chronic granulomatous disease, chronic inflammation, or autoimmune lymphoproliferative syndrome.

IgG subclass measurements are seldom helpful in assessing immune function in children with recurrent infections. It is difficult to know the biologic significance of the various mild to moderate deficiencies in IgG subclass measurements. These deficiencies have been described in children with atopic dermatitis, dermatitis herpetiformis, and rheumatologic disease. However, the more important factors are the underlying condition that led to the deficiency and the response to therapy.

Many healthy children have been described as having low levels of IgG, but normal responses to polysaccharide antigens when immunized. When children with low IgG subclass levels and histories of

ADA, Adenosine deaminase deficiency; AID, activation-induced cytidine deaminase; ALPS, autoimmune lymphoproliferative syndrome; CVID, common variable immunodeficiency; GVDH, graft-vs-host disease; Ig, immunoglobulin; IPEX, X-linked immune dysfunction enteropathy polyendocrinopathy; SCID, severe combined immunodeficiency.

frequent infections were studied in depth, they were found to have broader immunologic dysfunction, including poor responses to protein antigens, suggesting that they may have been in the process of developing into common variable immunodeficiency (CVID). Only when profound antibody deficiencies are detected despite normal levels of immunoglobulins are IgG subclass measurements occasionally helpful. Children who completely lack IgG2 are usually unable to make antibodies to polysaccharide antigens, although this may also be found among individuals with normal IgG2. Thus, specific antibody measurements are far more cost-effective than IgG subclass determinations.

Patients found to be agammaglobulinemic should have their blood B cells enumerated by flow cytometry using dye-conjugated monoclonal antibodies to B-cell–specific CD antigens (usually CD19 or CD20). Normally, approximately 8-10% of circulating lymphocytes are B cells. B cells are absent in X-linked agammaglobulinemia (XLA) and in several very rare autosomal recessive conditions, but they are present in CVID, IgA deficiency, and hyper-IgM syndromes. This distinction is important, because children with hypogammaglobulinemia from XLA and CVID can have different clinical problems, and the 2 conditions clearly have different inheritance patterns. Patients with XLA have a heightened susceptibility to persistent enteroviral infections, whereas those with CVID have more problems with autoimmune diseases and lymphoid hyperplasia. Molecular testing for XLA and other B-cell defects (see Chapter 124.1) is indicated in cases without a family history to aid genetic counseling.

T CELLS

T cells and T-cell subpopulations can be enumerated by flow cytometry using dye-conjugated monoclonal antibodies recognizing CD antigens present on T cells (i.e., CD2, CD3, CD4, and CD8). This is a particularly important test to perform on any infant who is lymphopenic, because CD3\(^+\) T cells usually constitute 70% of peripheral lymphocytes. Regardless of molecular type, infants with SCID are unable to produce T cells so are lymphopenic at birth. The flow cytometry for infants suspected of having SCID should also include monoclonal antibodies to naïve (CD45RA) and memory (CD45RO) T cells. In normal infants, more than 95% of the T cells are CD45RA\(^+\) (naïve) T cells. If the infant is a SCID, there could be transplacentally transferred maternal T cells detected by flow cytometry, but they would be dominantly CD45RO\(^+\) T cells. SCID is a pediatric emergency that can be

successfully treated by nonablative stem cell transplantation in more than 92% of cases if diagnosed before serious, untreatable infections develop. Normally, there are roughly twice as many CD4+ (helper) T cells as there are CD8+ (cytotoxic) T cells. Because there are examples of severe immunodeficiency in which phenotypically normal T cells are present, tests of T-cell function are far more informative and cost-effective than enumeration of T-cell subpopulations by flow cytometry. T cells are normally stimulated through their T-cell receptors by antigen present in the groove of major histocompatibility complex molecules. The T-cell receptor can also be stimulated directly with mitogens such as phytohemagglutinin, concanavalin A, or pokeweed mitogen. After 3-5 days of incubation with the mitogen, the proliferation of T cells is measured by the incorporation of radiolabeled thymidine into DNA. Other stimulants that can be used to assess T-cell function in the same type of assay include antigens (Candida, tetanus toxoid) and allogeneic cells (see Table 122-6).

**NATURAL KILLER CELLS**
Natural killer (NK) cells can be enumerated by flow cytometry using monoclonal antibodies to NK-specific CD antigens, CD16 and CD56. NK function is assessed by a radiolabeled chromium-release assay, using the cell line K562, which is readily killed by NK cells.

**PHAGOCYTIC CELLS**
Killing defects of phagocytic cells, which should be suspected if a patient has recurrent staphylococcal abscesses or gram-negative infections, can be evaluated by screening tests measuring the neutrophil respiratory burst after phorbol ester stimulation. The most reliable and useful test of this type is a flow cytometric assessment of the respiratory burst using rhodamine dye. Leukocyte adhesion deficiencies can be easily diagnosed by flow cytometric assays of blood lymphocytes or neutrophils, using monoclonal antibodies to CD18 or CD11 (LAD1) or to CD15 (LAD2).

Phagocytic cell defects can be further defined according to their molecular cause. Mutations in the genes encoding 5 different components of the NADPH pathway have been discovered in various patients with chronic granulomatous disease. It is important to identify the specific molecular type of chronic granulomatosus disease to provide appropriate genetic counseling, as 1 type is X linked and the other 4 types are autosomal recessive. Early diagnosis of leukocyte adhesion deficiency is of crucial importance because stem cell transplantation can be lifesaving.

**COMPLEMENT**
The most effective screening test for complement defects is a CH50 assay, which is a bioassay that measures the intactness of the entire complement pathway and yields abnormal results if complement has been consumed from the specimen for any reason. Genetic deficiencies in the complement system are usually characterized by extremely low CH50 values. The most common cause of an abnormal CH50 result, however, is a delay in or improper transport of the specimen to the laboratory. Specific immunoassays for C3 and C4 are commercially available, but further identification of other complement component deficiencies is usually possible only in research laboratories. Nevertheless, it is extremely important to identify which component is missing, because there are different disease susceptibilities depending on whether there are deficiencies of early or late components (see Chapter 134). Identifying the mode of inheritance is also important for genetic counseling. Properdin deficiency is X linked, but all of the other complement deficiencies are autosomal. Measurement of C4 can be helpful in assessing suspected hereditary angioedema.

Bibliography

Defense against infectious agents is secured through a combination of anatomic physical barriers including the skin, mucous membranes, mucous blanket, and ciliated epithelial cells, as well as the various components of the immune system. The *immune system* of vertebrates integrates 2 fundamental response mechanisms. **Innate (natural) immunity** responds to infection regardless of previous exposure to the agent and includes polymorphonuclear leukocytes, dendritic and mononuclear phagocytic cells, natural killer (NK) cells, various receptors that recognize common pathogen antigens (Toll-like receptors) and the complement system. **Acquired (adaptive) immunity** is a highly specific response that includes T and B lymphocytes. The immune system also helps protect against malignancy and autoimmunity.

**LYMPHOPOIESIS IN THE FETUS**

**Origin of the Lymphoid System**

The human immune system arises in the embryo from gut-associated tissue. Pluripotential hematopoietic stem cells first appear in the yolk sac at 2.5-3 wk of gestational age, migrate to the fetal liver at 5 wk of gestation, and later reside in the bone marrow, where they remain throughout life (Fig. 123-1). Lymphoid stem cells develop from such precursor cells and differentiate into T, B, or NK cells, depending on the organs or tissues to which the stem cells traffic. Development of the *primary lymphoid organs*—thymus and bone marrow—begins during the middle of the 1st trimester of gestation and proceeds rapidly. Development of the *secondary lymphoid organs*—spleen, lymph nodes, tonsils, Peyer patches, and lamina propria—soon follows. These organs serve as sites of differentiation of T, B, and NK lymphocytes from stem cells throughout life. Both the initial organogenesis and the continued cell differentiation occur as a consequence of the interaction of a vast array of lymphocytic and microenvironmental cell surface molecules and proteins secreted by the involved cells. The complexity and number of lymphoid cell surface molecules led to the development of an international nomenclature for *clusters of differentiation* (CD) (Table 123-1).

T and B lymphocytes are the only components of the immune system that have antigen-specific recognition capabilities and are responsible for adaptive immunity. NK cells are lymphocytes that are also derived from hematopoietic stem cells and are thought to have a role in host defense against viral infections, tumor surveillance, and immune regulation, but they do not have antigen receptors. Nonantibody proteins synthesized and secreted by T, B, and NK cells, and by the cells with which they interact, act as intercellular mediators and are referred to as *cytokines* or *interleukins* (ILs) (Table 123-2). Cytokines have the ability to act in an autocrine, paracrine, or endocrine manner...
By 12 wk gestation, T cells can proliferate. TCR gene rearrangement begins shortly after colonization of the thymus with stem cells, and the establishment of the T-cell repertoire begins at 8-10 wk of gestation. The mature TCR is a heterodimer of 2 chains, either α and β or γ and δ, that is coexpressed on the cell surface with CD3, a complex of 5 polypeptide chains (γ, δ, ε, ε, η). TCR gene rearrangement occurs by a process in which large, noncontiguous blocks of DNA are spliced together. These segments, known as V (variable), D (diversity), and J (joining), each have a number of variants. VD segments are joined to a constant region of the α gene, and VD segments are joined to the β gene to complete the receptor polypeptide genes. Random combinations of the segments account for much of the enormous diversity of TCRs that enables humans to recognize millions of different antigens. TCR gene rearrangement requires the presence of recombine activating genes, RAG-1 and RAG-2, as well as other recombinase components. This process is flawed in both mice and humans with severe combined immunodeficiency (SCID) because of mutations in genes that encode components of the VDJ recombination process. By 9.5-10 wk, more than 95% of thymocytes express CD2, CD4, CD7, CD8, and c (cytoplasmic) CD3, and ≈30% bear the CD1 inner cortical thymocyte antigen. By 10 wk, 25% of thymocytes bear αβ TCRs. T αβ T cells gradually increase in number during embryonic life and represent more than 95% of thymocytes postnatally.

As immature cortical thymocytes begin to express TCRs, the processes of positive and negative selection take place. Positive selection occurs through the interaction of immature thymocytes, which express low levels of TCR, with major histocompatibility complex (MHC) antigens present on cortical thymic epithelial cells. As a result, thymocytes with TCR capable of interacting with foreign antigens presented on self human leukocyte antigen (HLA) molecules are activated and develop to maturity. Most (>98%) of the cells die by failing to be positively selected or as a consequence of negative selection, but some are selected to mature into CD4 or CD8 single positive cells. Mature thymocytes that survive the selection process either express CD4 and are restricted to interacting with self class II HLA antigens, or express CD8 and are restricted to interacting with self class I HLA antigens when foreign antigens are presented by these MHC molecules. Negative selection occurs next in the medulla and is mediated by interaction of the surviving thymocytes, which have much higher levels of TCR expression, with host peptides presented by HLA class I or II antigens present on bone marrow-derived thymic macrophages, dendritic cells, and possibly B cells. This interaction mediates apoptosis (programmed cell death) of such autoreactive thymocytes. The thymic medulla contains only mature single-positive T cells that eventually leave the thymus and enter the bloodstream. T-cell functions are acquired concomitantly with the development of single-positive thymocytes, but they are not fully developed until the cells emigrate from the thymus. T cells begin to emigrate from the thymus to the spleen, lymph nodes, and appendix at 11-12 wk of embryonic life, and to the tonsils by 14-15 wk. They leave the thymus via the bloodstream and are distributed throughout the body, with the heaviest concentrations in the paracortical areas of lymph nodes, the parieteriolar areas of the spleen, and the thoracic duct lymph. Recent thymic emigrants coexpress the CD45RA isoforms and CD62L (l-selectin). Rearrangement of the TCR locus during intrathymic T-cell development results in the excision of DNA and the excised elements form circular episomes as a by-product. These TCR recombination excision circles can be detected in T cells that are recent thymic emigrants, whereas T cells that develop extrathymically do not contain these episomes. Inability to detect TCR recombination excision circles by real-time polymerase chain reaction of DNA from the dried blood spots collected from infants shortly after birth is the test used for newborn screening for SCID. The homing of lymphocytes to peripheral lymphoid organs is directed by the interaction of a lymphocyte surface adhesion molecule, l-selectin, with carbohydrate moieties on specialized regions of lymphoid organ blood vessels called high endothelial venules. By 12 wk gestation, T cells can proliferate in response to plant lectins, such as phytohemagglutinin and concanavalin A, and to allogeneic cells; antigen-binding T cells have been found by 20 wk gestation. Hassall’s corpuscles (bodies), which are swirls of terminally differentiated medullary epithelial cells, are first seen in the thymic medulla at 16-18 wk of embryonic life.

</table>

AMP, Adenosine monophosphate; CD, cluster of differentiation; EBV, Epstein-Barr virus; HLA, human leukocyte antigen; ICAM, intracellular adhesion molecule; ICOS, inducible costimulator; Ig, immunoglobulin; IL, interleukin; LFA, lymphocyte function-associated antigen; MAC, membrane attack complex; NCAM, neural cell adhesion molecule; NK, natural killer; SRBC, sheep red blood cell; TCR, T-cell receptor.

### B-Cell Development and Differentiation

In parallel with T-cell differentiation, B-cell development begins in the fetal liver before 7 wk of gestation. Fetal liver CD34 stem cells are seeded to the bone marrow of the clavicles by 8 wk of embryonic life and to that of the long bones by 10 wk (see Fig. 123-1). As B cells differentiate from primitive stem cells, they proceed through stages that are marked by the sequential rearrangement of immunoglobulin gene segments to generate a diverse repertoire of antigen receptors. The early pro-B cell is the first descendnt of the pluripotential stem cell committed to B-lineage development and in this stage, the heavy chain locus rearranges first. In the early pro-B cell, D-J rearrangements are made on both chromosomes. In the late pro-B cell, the V segment rearranges to a D-J gene segment, but it is a matter of chance whether the juxtaposed J sequence and the μ constant region sequence downstream can be read in the correct reading frame. There is a roughly 2 in 3 chance that an out-of-frame sequence will occur,
Table 123-2  Functional Classification of Cytokines

1. Cytokines involved in natural immune responses
   - Type I interferons (IFN-α and IFN-β): inhibit viral replication, inhibit cell proliferation, activate NK cells, and upregulate class I MHC molecule expression
   - TNF-α: mediates host response to Gram-negative bacteria and other infectious agents
   - IL-1α and -1β: mediate host inflammatory response to infectious agents
   - IL-1Ra: a natural antagonist of IL-1, blocks signals delivered by IL-1
   - IL-6: mediates and regulates inflammatory responses
   - Chemokines (IL-8, monocyte chemotactic protein-1 or MCP-1, RANTES, and others): mediate leukocyte chemotaxis and activation

2. Lymphocyte regulatory cytokines
   a. Immunostimulatory or growth-promoting
      - IL-1: costimulates activation of T cells
      - IL-2: growth factor for T, B, NK cells; activates NK and T effector cells
      - IL-4: T- and B-cell growth factor; stimulates IgE production; upregulates classes I and II MHC molecules and FcRν expression on macrophages; expansion of Th2 subset
      - IL-5: B-cell growth and activation
      - IL-6: growth factor for B cells
      - IL-7: stromal cell factor; growth factor for precursor B and T cells, T-cell homeostatic factor
      - IL-10: growth and differentiation factor for B cells
      - IL-12: expansion of Th1 subset; activates effector cells
      - IL-13: growth and differentiating factor for B cells; stimulates IgE production; upregulates Classes I and II MHC molecules and FcRν expression on macrophages
      - TNF-β: stimulates effector cell function
      - IL-15: regulates NK-cell development and memory cell homeostasis
      - IL-17: promotes inflammation by acting on local tissue cells to cause them to produce chemokines, such as IL-8, that recruit neutrophils and other innate effector cells
      - IL-18: induces IFN-γ, GM-CSF, TNF-α in immunocompetent cells
      - IL-21: together with IL-4 regulates IgG and IgE class-switching and Ig synthesis
      - IL-23: autocrine growth factor for Th17 cells
      - IL-27: produced by antigen presenting cells and regulates both T and B cell activity
      - IFN-γ: activates macrophages, NK cells; upregulates classes I and II MHC molecules expression; inhibits IL-4– or IL-13-induced IgE production
   b. Immunosuppressive
      - IL-1Ra: regulates IL-1 activities
      - TGF-β: antagonizes lymphocyte responses
      - IL-10: inhibits activities of Th1 cells
      - IFN-α/β: inhibits production of IFN-γ

3. Hematopoiesis regulating cytokines
   - GM-CSF, G-CSF, M-CSF: colony-stimulating factors
   - Erythropoietin (EPO): differentiation of erythroid precursors
   - IL-3, SCF, c-kit receptor: regulate stem cell development
   - IL-4: mast cell development
   - IL-5: eosinophil differentiation and proliferation
   - IL-6: differentiation of B cells
   - IL-7: differentiation of B and T cells
   - IL-8: promotes cell survival in response to hematopoietic cytokines
   - IL-9: mast-cell growth factor
   - IL-11: elevates platelet count in patients given chemotherapy
   - IL-12: expands and activates resting NK cells
   - IL-15: expands and activates resting NK cells
   - IL-21: limits viability of NK cells

4. Proinflammatory cytokines
   - IL-1, TNF-α, IL-6: participate in the acute-phase response and synergize to mediate inflammation, shock, and death
   - IL-12: stimulates IFN-γ (production by T and NK cells)
   - IL-17: acts on monocytes to induce secretion of proinflammatory mediators such as IL-8, TNF, and GM-CSF
   - IL-18: induces IFN-γ, GM-CSF, TNF-α; upregulates chemokine receptors
   - IL-23: drives the development of autoreactive IL-17–producing T cells and promotes chronic inflammation

5. Antinflammatory cytokines
   - IL-4: reduces endotoxin-induced TNF and IL-1 production
   - IL-6: inhibits TNF production
   - IL-10: suppresses lymphocyte functions and downregulates production of proinflammatory cytokines; antiatherogenic
   - IL-11: cytotoxic effect on bowel mucosa, skin and joint inflammation
   - IL-13: downregulates functions of macrophages, suppresses production of proinflammatory cytokines
   - TGF-β: has immunosuppressive effects, inhibits IL-1 and TNF gene expression
   - IL-1Ra: competes with the binding of IL-1 to its cell surface receptors and blocks IL-1R
   - TNFSR: soluble TNF receptor; by binding TNF, blocks interaction of TNF with the target cell

*This is not an exhaustive list.

G-CSF, Granulocyte colony-stimulating factor; GM-CSF, granulocyte macrophage colony-stimulating factor; IFN, interferon; Ig, immunoglobulin; IL, interleukin; IL-1R, interleukin-1 receptor; M-CSF, macrophage colony-stimulating factor; MHC, major histocompatibility complex; MCP-1, monocyte chemotactic protein; NK, natural killer; RANTES, regulated on activation normal t cell expressed and secreted; SCF, stem cell factor; TGF, transforming growth factor; Th1, Th2, Th17, T-helper types 1, 2, and 17; TNF, tumor necrosis factor.

and only those cells that have productive rearrangements will survive, so a majority of cells are lost. The next stage is the pre-B cell, during which immunoglobulin (Ig) light chain genes are rearranged. The pre-B cell is distinguished by the expression of cytoplasmic μ heavy chains but no slgM, because immunoglobulin light chains are not yet produced. The pre-B cells must rearrange the same light chain gene on both chromosomes for a productive rearrangement, so when this does not happen the cells are lost. Fewer cells are lost between the pre-B and immature B cell stages than in the pro-B to pre-B transition. Next is the immature B-cell stage, during which the light-chain genes have already been rearranged and slgM but not slgD is expressed. The last stage of antigen-independent B-cell development is the mature or virgin B cell, which co-expresses both slgM and slgD. Pre-B cells can be found in fetal liver at 7 wk gestation, slgM+ and slgG+ B cells at between 7 and 11 wk, and slgD+ and slgA+ B cells by 12-13 wk. By 14 wk of embryonic life, the percentage of circulating lymphocytes bearing slgM and slgD is the same as in cord blood and slightly higher than in the blood of adults.

Antigen-dependent stages of B-cell development are those that develop after the mature or virgin B cell is stimulated by antigen through its antigen receptor (slg); the outcome is the differentiation of the cell and its progeny into slg+ memory (CD27) B cells (for that particular antigen) and plasma cells, which synthesize and secrete antibody, which is antigen-specific immunoglobulin. Deficiency of activation-induced cytide deaminase (AI/CDA) or of uracil DNA glycosylase (UNG), as seen in 2 forms of autosomal recessive hyper IgM, can result in a failure of isotype switching so that only IgM antibodies are formed.

There are 5 immunoglobulin isotypes, which are defined by unique heavy-chains: IgM, IgG, IgA, IgD, and IgE. IgG and IgM, the only complement-fixing isotypes, are the most important immunoglobulins in the blood and other internal body fluids for protection against infectious agents. IgM is confined primarily to the extravascular compartment because of its large size, whereas IgG is present in all internal body fluids. IgA is the major protective immunoglobulin of external secretions—in the gastrointestinal, respiratory, and urogenital tracts—but it is also present in the circulation. IgE, present in both internal and external body fluids, has a major role in host defense against parasites. Because of high-affinity IgE receptors on basophils and mast cells, however, IgE is the principal mediator of allergic reactions of the immediate type. The significance of IgD is still not clear. There are also 2 immunoglobulin subclasses including 4 subclasses of IgG (IgG1, IgG2, IgG3, and IgG4) and 2 subclasses of IgA (IgA1 and IgA2). These subclasses each have different biologic roles. For example, antipoly saccharide antibody activity is found predominantly in the IgG1 subclass. Secreted IgM and IgE have been found in abortuses as young as 10 wk, and IgG as early as 11-12 wk. Even though these B-cell developmental stages have been described in the context of B-cell ontogeny in utero, it is important to recognize that the process of B-cell development from pluripotential stem cells goes on throughout postnatal life. Despite the capacity of fetal B lymphocytes to differentiate into immunoglobulin-synthesizing and -secreting cells, plasma cells are not usually found in lymphoid tissues of a fetus until about 20 wk gestation, and then only rarely, because of the sterile environment of the uterus. Peyer patches have been found in significant numbers by the 5th intrauterine mo, and plasma cells have been seen in the lamina propria by 25 wk gestation. Before birth there may be primary follicles in lymph nodes, but secondary follicles are usually not present.

A human fetus begins to receive significant quantities of maternal IgG transplacentally at around 12 wk gestation, and the quantity steadily increases until, at birth, cord serum contains a concentration of IgG comparable to or greater than that of maternal serum. IgG is the only class to cross the placenta to any significant degree. All 4 IgG subclasses cross the placenta, but IgG2 does so least well. A small amount of IgM (10% of adult levels) and a few nanograms of IgA, IgD, and IgE are normally found in cord serum. Because none of these proteins crosses the placenta, they are presumed to be of fetal origin. These observations raise the possibility that certain antigenic stimuli normally cross the placenta to provoke responses, even in uninfected fetuses. Some atopic infants occasionally have IgE antibodies to antigens, such as egg white, to which they have had no known exposure during postnatal life, suggesting that synthesis of these antibodies could have been induced in the fetus by antigens ingested by the mother.

Natural Killer–Cell Development

NK cell activity is found in human fetal liver cells at 8-11 wk of gestation. NK lymphocytes are also derived from bone marrow precursors. THymic processing is not necessary for NK-cell development, although NK cells have been found in the thymus. After release from bone marrow, NK cells enter the circulation or migrate to the spleen, with very few NK cells in lymph nodes. In normal individuals, NK cells represent 8-10% of lymphocytes, but the percentages are sometimes slightly lower in cord blood.

Unlike T and B cells, NK cells do not rearrange antigen receptor genes during their development but are defined by their functional capacity to mediate non–antigen-specific cytotoxicity. NK cells have killer inhibitory receptors that recognize certain MHC antigens and inhibit the killing of normal allogeneic cells in 4 specific patterns of reactivity. The genetic loci controlling these receptors are different from MHC alloantigenic loci, and have been mapped to chromosome 19. Virtually all NK cells express CD56, and more than 90% bear CD16 (FcγRIII) on the cell surface. Other CD antigens found on NK cells include CD57 (50-60%), CD7 and CD2 (70-90%), and CD8 (30-40%) (see Table 123-1). Although NK cells share surface antigens with T and myeloid cells, the lineage relationship of NK cells to the latter is still unclear. Some humans with autosomal recessive SCID who have profound deficiencies in T and B cells, have abundant NK cells, whereas those with X-linked and Jak3-deficient SCID have no T or NK cells.

Immune Cell Interactions

Immune cell interaction is of crucial importance to all phases of the adaptive immune response. Unlike the B-cell antigen receptor (Ig), which can recognize native antigen, the TCR can recognize only processed antigenic peptides presented to it by MHC molecules such as HLA-A, -B, and -C antigens (class I) and HLA-DR, -DP, and -DQ antigens (class II). The MHC molecules have a groove in their protein structure where peptides fit. Class I MHC molecules are found on most nucleated cells in the body. Class II MHC molecules are found on antigen-presenting cells (APCs), which include macrophages, dendritic cells, and B cells. The peptides found in the groove of class I HLA molecules come from proteins normally made in the cell that are degraded and inserted into the groove. The peptides include viral peptides if the cell is infected with a virus. The peptides present in the groove of class II molecules come from exogenous native antigens such as vaccine and bacterial proteins. These proteins are taken up by APCs, degraded, and expressed on the cell surface in the groove of class II HLA molecules. The TCR then interacts with the peptide-bearing HLA molecule and, through its functional and physical link to the CD3 complex of signal-transducing molecules, sends a signal to the T cell to produce cytokines that ultimately result in T-cell activation and proliferation.

Two of the main functions of T cells are to signal B cells to make antibody by producing cytokines and membrane molecules that can serve as ligands for non–antigen-receptor B-cell surface molecules and to kill virally infected cells or tumor cells. For a T cell to perform either of these functions, it first must bind to an APC or to a target cell (the immunologic synapse). For high-affinity binding of T cells to APCs or target cells, several molecules on T cells, in addition to TCRs, bind to molecules on APCs or target cells. The CD4 molecule binds directly to MHC class II molecules on APCs. CD8 on cytotoxic T cells binds the MHC class I molecule on the target cell. Both CD4 and CD8 molecules are directly involved in the regulation of T-cell activation and are physically linked intracellularly to the p56-lck protein tyrosine kinase. The cytoplasmic tail of CD45, the common leukocyte antigen, is a tyrosine phosphatase capable of regulating T-cell signal-transduction events by virtue of the fact that p56-lck is a substrate for CD45 phosphatase activity. Depending on which isoform of CD45 is present on
the T cell (CD45RO on memory T cells, CD45RA on naïve T cells), mechanisms by which CD45 could upregulate or downregulate T-cell triggering have been proposed. Indeed, one form of human SCID is caused by a deficiency of CD45. Lymphocyte function-associated antigen 1 (LFA-1) on the T cell binds a protein called ICAM-1 (intracellular adhesion molecule 1), designated CD54, on APCs. CD2 on T cells binds LFA-3 (CD58) on the APCs. With the adhesion of T cells to APCs (the immunologic synapse), T-helper (Th) cells are stimulated to make interleukins and upregulate cell surface molecules, such as the CD40 ligand (CD154), that provide help for B cells, and cytotoxic T cells are stimulated to kill their targets.

In the primary antibody response, naïve antigen is carried to a lymph node draining the site, taken up by specialized cells called follicular dendritic cells (FDCs), and expressed on their surfaces. Virgin B cells bearing slg specific for that antigen then bind to the antigen on the surfaces of the FDCs. If the affinity of the B-cell slg antibody for the antigen present on the FDCs is sufficient, and if other signals are provided by activated Th cells, the B cell develops into an antibody-producing plasma cell. If the affinity is not high enough or if T-cell signals are not received, the B cell dies through apoptosis. The signals from activated Th cells include several cytokines (IL-4, IL-5, IL-6, IL-10, IL-13, and IL-21) that they secrete (see Table 123-2) and a surface T-cell molecule, the CD40 ligand or CD154, which, on contact of the activated CD4 positive T cell with the B cell, binds to CD40 on the B-cell surface. CD40 is a type I integral membrane glycoprotein expressed on B cells, monocytes, some carcinomas, and a few other types of cells. It belongs to the tumor necrosis factor/nerve growth factor receptor family. Crosslinking of CD40 on B cells by CD154 on T cells in the presence of certain cytokines causes the B cells to undergo proliferation and to initiate immunoglobulin synthesis. In the primary immune response, only IgM antibody is usually made, and most of it is of relatively low affinity. Some B cells become memory B cells during the primary immune response. These cells switch their immunoglobulin genes so that IgG, IgA, and/or IgE antibodies of higher affinity are formed on a secondary exposure to the same antigen. The secondary antibody response occurs when these memory B cells again encounter that antigen. Plasma cells form, just as in the primary response; however, many more cells are rapidly generated, and IgG, IgA, and IgE antibodies are made. In addition, genetic changes in immunoglobulin genes (somatic hypermutation) lead to increased affinity of those antibodies. A lack of somatic hypermutation is seen in deficiency of activation-induced cytidine deaminase (AID) or uracil-N-glycosylase (UNG). The exact pattern of isotype response to antigen in normal individuals varies, depending on the type of antigen and the cytokines present in the microenvironment.

For NK-mediated lysis, binding to the target is of crucial importance. This is best exemplified by persons with leukocyte adhesion deficiency type 1 (LAD-1) who have mutations in the gene encoding CD18, or the β chain of 3 different adhesion molecules (LFA-1, CR3, and p150,95), and who lack NK function. Thus, binding of NK cells to their targets is facilitated by LFA-1-ICAM interactions. CD56 or NCAM (neural cell adhesion molecule) also mediates homotypic adhesion of NK cells. FcyRIII, or the low-affinity IgG receptor, has a higher affinity for IgG when it is present on NK cells than when it is on neutrophils. FcyRIII also permits NK cells to mediate antibody-dependent cellular cytotoxicity, where antibody is bound through its Fc region to the FcγRIII. The antibody-combining portion of the IgG attaches to the target cell, and the NK cell, attached to the target by the Fc portion of the antibody, kills the target cell.

**POSTNATAL LYMPHOPHOESIS**

### T Cells and T-Cell Subsets

Although the percentage of CD3 T cells in cord blood is somewhat less than in the peripheral blood of children and adults, T cells are actually present in higher number because of a higher absolute lymphocyte count in normal infants. An additional distinction is that the ratio of CD4 to CD8 T cells is usually higher (3.5-4:1) in cord blood than in blood of children and adults (1.5-2:1). Virtually all T cells in cord blood bear the CD45RA ( naïve) isofrom, and a dominance of CD45RA over CD45RO T cells persists during the 1st 2-3 yr of life, after which time the numbers of cells bearing these 2 isofroms gradually equalize. Th cells can be further subdivided according to the cytokines they produce when activated. **Th1 cells** produce IL-2 and IFN-γ, which promote cytotoxic T-cell or delayed hypersensitivity types of responses, whereas **Th2 cells** produce IL-4, IL-5, IL-6, IL-13, and IL-21 (see Table 123-2), which promote B-cell responses and allergic sensitization, and **Th17 cells** produce IL-17. Development of Th cells into Th17 cells occurs when IL-6 and transforming growth factor β are present but IL-4 and IL-12 are absent. Th17 cells produce IL-21, which acts in an autocrine manner to activate STAT3, a transcription factor required for their further development as Th17 cells. Th17 cells express the receptor for the cytokine IL-23, stimulation that is required for development of Th17 effector activity. Th17 promotes inflammation by acting on local tissue cells to cause them to produce chemokines, such as IL-8, that recruit neutrophils and other innate effector cells. It is thought that the absence of these cells in the autosomal dominant form of the hyper-IgE syndrome (see Chapter 126) accounts for those patients' infection susceptibility to *Candida*. There are important additional subsets of T cells that have regulatory functions. These include CD25 high + T cells (*Treg cells*), also characterized by the presence of FOXP3 (absent in IPEX syndrome [see Chapter 126]) and considered to be important in the prevention of autoimmune diseases, and T cells that have phenotypic characteristics of NK cells (NKT cells). Cord blood T cells have the capacity to respond normally to T-cell mitogens (*phytohemagglutinin, concanavalin A, and pokeweed mitogen*) and are capable of mounting a normal mixed leukocyte response. Normal newborn infants also have the capacity to develop antigen-specific T-cell responses at birth, as evidenced by vigorous tuberculin reactivity a few wk after bacillus Calmette-Guérin vaccination on day 1 of life. Because patients in the 1st few mo of life may have unrecognized severe T-cell defects, most hospitals now routinely irradiate all blood products given young infants. T-cell defects can readily be detected even at birth by calculating the absolute lymphocyte count because T cells normally constitute 70% of circulating lymphocytes and their absence results in striking lymphopenia (see Fig. 122-2). T-cell lymphopenia also serves as the basis for the currently used newborn screening test for SCID.

### B Cells and Immunoglobulins

Newborn infants have increased susceptibility to infections with Gram-negative organisms because IgM antibodies, which are heat-stable opsonins, do not cross the placenta. The level of the heat-labile opsonin, C3b, is also lower in newborn serum than in adults. These factors probably account for impaired phagocytosis of some organisms by newborn polymorphonuclear cells. Maternally transmitted IgG antibodies serve quite adequately as heat-stable opsonins for most *Candida*-positive bacteria, and IgG antibodies afford adequate protection against those agents. Because there is a relative deficiency of the IgG1 subclass, antibodies to capsular polysaccharide antigens may be deficient. Because premature infants have received less maternal IgG by the time of birth than full-term infants, their serum opsonic activity is low for all types of organisms.

B lymphocytes are present in cord blood in slightly higher percentages but considerably higher numbers than in the blood of children and adults, reflecting the higher absolute lymphocyte counts in all normal infants. Cord blood B cells do not synthesize the range of immunoglobulin isotypes made by B cells from children and adults when stimulated with anti-CD40 plus IL-4 or IL-10, producing primarily IgM and at a much reduced quantity. Neonates begin to synthesize antibodies of the IgM class at an increased rate very soon after birth in response to the immense antigenic stimulation of their new environment. Premature infants appear to be as capable of doing this as do full-term infants. At about 6 days after birth, the serum concentration of IgM rises sharply. This rise continues until adult levels are achieved by ~1 yr of age. Cord serum from noninfected normal newborns does not contain detectable IgA. Serum IgA is normally first detected at around the 13th day of postnatal life; the level gradually increases during early childhood until adult levels are achieved by 6-7 yr of age. Cord serum contains an IgG...
concentration comparable to or greater than that of maternal serum. Maternal IgG gradually disappears during the 1st 6-8 mo of life, while the rate of infant IgG synthesis increases (IgG1 and IgG3 faster than IgG2 and IgG4, during the 1st yr) until adult concentrations of total IgG are reached and maintained by 7-8 yr of age. IgG1 and IgG3 reach adult levels first, followed by IgG3, at 10 yr and IgG2, at 12 yr of age. The serum IgG level in infants usually reaches a low point at ≈3-4 mo of postnatal life. The rate of development of IgE generally follows that of IgA. After adult concentrations of each of the 3 major immunoglobulins are reached, these levels remain remarkably constant for a normal individual. The capacity to produce specific antibodies to protein antigens is intact at the time of birth. Normal infants cannot usually produce antibodies to polysaccharide antigens until after 2 yr of age unless the polysaccharide is conjugated to a protein carrier, as is the case for the conjugate Haemophilus influenzae type b and Streptococcus pneumoniae vaccines.

Natural Killer Cells
The percentage of NK cells in cord blood is usually lower than in the blood of children and adults, but the absolute number of NK cells is approximately the same, owing to the higher lymphocyte count. The capacity of cord blood NK cells to mediate target lysis in either NK-cell assays or antibody-dependent cellular cytotoxicity assays is roughly two-thirds that of adults.

Lymphoid Organ Development
Lymphoid tissue is proportionally small but rather well developed at birth and matures rapidly in the postnatal period. The thymus is largest relative to body size during fetal life and at birth is ordinarily two-thirds that of its mature weight, which it attains during the 1st yr of life. It reaches its peak mass, however, just before puberty, and then gradually involutes thereafter. By 1 yr of age, all lymphoid structures are mature histologically. Absolute lymphocyte counts in the peripheral blood also reach a peak during the 1st yr of life (see Fig. 122-2). Peripheral lymphoid tissue increases rapidly in mass during infancy and early childhood. It reaches adult size by approximately 6 yr of age, exceeds those dimensions during the prepuberlal years, and then undergoes involution coincident with puberty. The spleen, however, gradually accretes its mass during maturation and does not reach full weight until adulthood. The mean number of Peyer patches at birth is one-half the adult number, and gradually increases until the adult mean number is exceeded during adolescent years.

INHERITANCE OF ABNORMALITIES IN T-, B-, AND NATURAL KILLER–CELL DEVELOPMENT
More than 220 immunodeficiency syndromes have been described (see Table 122-8). Specific molecular defects have been identified in approximately 80% of these diseases. Most are recessive traits, several of which are caused by mutations in genes on the X chromosome and others by mutations on autosomal chromosomes. The molecular bases of 7 X-linked immunodeficiency disorders affecting T, B, and/or NK cells are known (see Chapters 124-126): X-linked immunodeficiency with hyper-IgM, X-linked lymphoproliferative syndrome, XIAD, X-linked agammaglobulinemia, X-linked SCID, the Wiskott-Aldrich syndrome, and nuclear factor kappa B essential modulator (NEMO). A few of the autosomal defects for which the molecular basis is known include (1) combined immunodeficiencies caused by abnormalities of purine salvage pathway enzymes, either adenosine deaminase (encoded by a gene on chromosome 20q13-ter) or purine nucleoside phosphorylase (encoded by a gene on chromosome 14q13.1); (2) combined immunodeficiencies caused by mutations in the gene encoding ZAP-70 (localized to chromosome 2q12), a non-src family protein tyrosine kinase important in T-cell signaling; (3) SCID caused by mutations in the gene on chromosome 19p13.1 encoding Janus kinase 3 (Jak3), the primary signal transducer from the common cytokine receptor γ chain (γc); (4) mutations in genes on chromosome 11 that encode components of the TCR, that is, CD3 γ, δ, and ε; (5) SCID caused by mutations in recombination activating genes (RAG1 and RAG2); and (6) SCID caused by mutations in the gene on chromosome 5p13 that encodes the α chain of the IL-7 receptor. These are only a few of the conditions for which the mutated genes have been discovered and the number is steadily growing.

PRENATAL DIAGNOSIS AND CARRIER DETECTION
Intrauterine diagnosis of adenosine deaminase and purine nucleoside phosphorylase deficiencies can be established by enzyme analyses on amnion cells (fresh or cultured) obtained before 20 wk gestation. Diagnosis of X-linked or autosomal defects causing SCID, other severe T-cell deficiencies, MHC class I and/or II antigen deficiencies, chronic granulomatous disease, or Wiskott-Aldrich syndrome can be established by direct mutation analysis of cells obtained by chorionic villus sampling or by amniocentesis if the mutation is known in the family or, if not known, by appropriate tests of phenotype or function on small samples of blood obtained by fetoscopy at 18-22 wk of gestation. The same diagnostic procedures can be performed on cord blood, but the only immunodeficiency disorder being routinely screened for is SCID and only 21 states are currently doing this (see Chapter 122). Carriers of any of these conditions can be identified by direct mutation analysis if the family's mutation is known.

Chapter 124
Primary Defects of Antibody Production
Rebecca H. Buckley

Of all of the primary immunodeficiency diseases, those affecting antibody production are most frequent. Selective absence of serum and secretory immunoglobulin (Ig)A is the most common defect, with rates ranging from 1 in 333 to 1 in 18,000 persons among different races and ethnicities. By contrast, agammaglobulinemia is estimated to occur with a frequency of only 1 in 10,000 to 1 in 50,000 persons. Patients with antibody deficiency are usually recognized because they have recurrent infections with encapsulated bacteria, predominantly in the upper and lower respiratory tracts; some individuals with selective IgA deficiency or infants with transient hypogammaglobulinemia may have few or no infections. The defective gene products for many primary antibody deficiency disorders have been identified (Table 124-1) and localized (Fig. 124-1). Sometimes the defect is not in the B cell itself but in T cells, which are required for complete B-cell function; some disorders are caused by unknown factors or are secondary to an underlying disease or its treatment (Table 124-2).

X-LINKED AGAMMAGLOBULINEMIA
Patients with X-linked agammaglobulinemia (XLA), or Bruton agammaglobulinemia, have a profound defect in B-lymphocyte development resulting in severe hypogammaglobulinemia, an absence of circulating B cells, small to absent tonsils, and no palpable lymph nodes.

Genetics and Pathogenesis
The abnormal gene in XLA maps to q22 on the long arm of the X chromosome and encodes the B-cell protein tyrosine kinase Btk (Bruton tyrosine kinase). Btk is a member of the Tec family of cytoplasmic protein tyrosine kinases and is expressed at high levels in all B-lineage cells, including pre-B cells. It appears to be necessary for
**Clinical Manifestations**

Most boys afflicted with XLA remain well during the 1st 6-9 mo of life by virtue of maternally transmitted IgG antibodies. Thereafter, they acquire infections with extracellular pyogenic organisms, such as *Streptococcus pneumoniae* and *Haemophilus influenzae*, unless they have given prophylactic antibiotics or immunoglobulin therapy. Infections include sinusitis, otitis media, pneumonia, or, less often, sepsis or meningitis. Infections with *Mycoplasma* are also particularly problematic. Chronic fungal infections are seen; *Pneumocystis jiroveci* pneumonia rarely occurs. Viral infections are usually handled normally with the exceptions of hepatitis viruses and enteroviruses. There were several examples of paralysis when live polio vaccine was administered to these patients, and chronic, eventually fatal, central nervous system infections with various echoviruses and coxsackieviruses have occurred in a significant number of them. Echovirus-associated dermatomyositis has also been observed. These observations suggest a primary role for antibody, particularly secretory IgA, in host defense against enteroviruses.

**Diagnosis**

The diagnosis of XLA should be suspected if lymphoid hypoplasia is found on physical examination (minimal or no tonsillar tissue and no

AID, Activation-inducible cytidine deaminase; BAFF-R, B-cell–activating factor of the tumor necrosis factor family receptor; Btk, Bruton tyrosine kinase; CVID, common variable immunodeficiency; EBNA, Epstein-Barr virus nuclear antigen; EBV, Epstein-Barr virus; HIGM, hyper-IgM syndrome; ICOS, inducible costimulatory; NEMO, nuclear factor κB essential modulator; PI3K, phosphatidylinositol 3 kinase; TACI, transmembrane activator, calcium modulator, and cyclophilin ligand interactor; UNG, uracil DNA glycosylase; XLA, X-linked agammaglobulinemia; XLP, X-linked lymphoproliferative disease.

pre-B-cell expansion and maturation into surface IgE-expressing B cells, but probably has a role at all stages of B-cell development; it has also been found in cells of the myeloid series. More than 500 different mutations in the human *Btk* gene are recognized; they encompass most parts of the coding portions of the gene. There is not a clear correlation between the location of the mutation and the clinical phenotype. Carriers are detected by mutation analysis, and prenatal diagnosis of the disorder is possible if the mutation is known in the family.

The expression of Btk in cells of myeloid lineage is of interest because boys with XLA often have neutropenia at the height of an acute infection. It is conceivable that Btk is only one of the signaling molecules participating in myeloid maturation and that neutropenia is observed in XLA only when rapid production of such cells is needed. Some pre-B cells are found in the bone marrow; the percentage of peripheral blood B lymphocytes is <1%. The percentage of T cells is increased, ratios of T-cell subsets are normal, and T-cell function is intact. The thymus is normal.

**Seven autosomal recessive defects** have also been shown to result in agammaglobulinemia with an absence of circulating B cells (Table 124-3), including mutations in the genes encoding: (1) the μ heavy chain gene; (2) the Igα and (3) Igβ signaling molecules; (4) B-cell linker adaptor protein (BLNK); (5) the surrogate light chain, λ5/14.1; (6) leucine-rich repeat-containing 8 (LRRC8); and (7) the p85α subunit of phosphatidylinositol-3 kinase.
Figure 124-1 The pre-B cell receives proliferation and differentiation signals through the pre-B-cell receptor (BCR) and the coreceptors Igα and Igβ. Signaling from the pre-BCR involves the immunoreceptor tyrosine-based activation motifs (ITAMs) of the coreceptors Igα and Igβ, which scaffold and activate the tyrosine kinase SYK. SYK either activates the extracellular signal-regulated kinase (ERK) pathway or phosphorylates (P) (together with LYN) the adaptor protein B-cell linker (BLNK) and Bruton's tyrosine kinase (BTK), leading to the activation of phospholipase Cγ2 (PLCγ2) and the phosphoinositide-3 kinase (PI3K) pathway. Defects in this pathway affect the pre-BCR (in C4 or pseudo light-chain λ5), the pre-BCR signal transduction molecules Igα and Igβ, the downstream molecules BTK, BLNK, and PI3K, components of the costimulatory CD19 complex (CD19, CD21, and CD81) and the B-cell marker CD20. The BCR triggers the canonical nuclear factor-xB (NF-xB) pathway through the scaffolding protein CARD11 and activation of the IκB kinase (IKK) complex (comprising IKKα, IKKβ, and NEMO [NF-xB essential modulator]). IKK activation leads to the phosphorylation and degradation of NF-xB inhibitor-α (IκBα) and the subsequent release of the p50-p65 NF-xB heterodimer, which then translocates to the nucleus to regulate gene transcription (not shown). Following antigen binding to antigen receptors (such as the BCR), endoplasmic reticulum Ca++ stores are depleted, STIM1 is activated and ORAI1 Ca++ release-activated Ca++ channels open, resulting in store-operated Ca++ entry. This influx results in activation of the transcription factor NFAT (nuclear factor of activated T cell). The dashed arrows indicate downstream signaling events. ER, endoplasmic reticulum; PAD, primary antibody deficiency; PtdIns(4,5)P$_2$, phosphatidylinositol-4,5-bisphosphate; PtdIns(3,4,5)P$_3$, phosphatidylinositol-3,4,5-trisphosphate.

COMMON VARIABLE IMMUNODEFICIENCY

Common variable immunodeficiency (CVID) is a syndrome characterized by hypogammaglobulinemia with phenotypically normal B cells. It has also been called acquired hypogammaglobulinemia because of a generally later age of onset of infections. CVID patients may appear similar clinically to those with XLA in the types of infections experienced and bacterial etiologic agents involved, except that echovirus meningoencephalitis is rare in patients with CVID (see Table 124-3). In contrast to XLA, the sex distribution in CVID is almost equal, the age at onset is later (although it may be present in infancy), and infections may be less severe.

Genetics and Pathogenesis

Most patients have no identified molecular diagnosis. CVID is a category of primary immunodeficiency disorders that likely consists of several different genetic defects with autosomal recessive or dominant inheritance. Genes known to produce the CVID phenotype when mutated include ICOS (inducible costimulator) deficiency, SP120A (responsible for X-linked lymphoproliferative disease [XLP]), CD19, CD20, CD21, CD81, BAFF-R (B-cell–activating factor of the tumor necrosis factor family receptors), TACI (transmembrane activator, calcium modulator, and cyclophilin ligand interactor), and 2 genes that encode DNA methyl transferase (DNMT3B and ZBTB24). These mutations in aggregate account for less than 10% of all cases of CVID. Because CVID occurs in 1st-degree relatives of patients with selective IgA deficiency, and some patients with IgA deficiency later become panhypogammaglobulinemic, a large subtype of CVID may have a common genetic basis with IgA deficiency. The high incidence of abnormal immunoglobulin concentrations, autoantibodies, autoimmune disease, and malignancy in both CVID and IgA deficiency and in other members of those patients' families also suggests a shared hereditary influence. This concept is supported by the discovery of a high incidence of C4-A gene deletions and C2 rare gene alleles in the class III major histocompatibility complex (MHC) region in individuals with either IgA deficiency or CVID, suggesting that a common susceptibility gene is on chromosome 6. Only a few human leukocyte antigen (HLA) haplotypes are shared by individuals affected with IgA deficiency and CVID, with at least 1 of 2 particular haplotypes being present in 77% of those affected. In 1 large family with 13 members, 2 had IgA deficiency and 3 had CVID. All of the immunodeficient patients in the family had at least 1 copy of an MHC haplotype that is abnormally frequent in IgA deficiency and CVID, suggesting that a common susceptibility gene is on chromosome 6p21 in the proximal part of the MHC was observed in a susceptibility locus now designated as IGD1. More sensitive genetic analysis in 101 multiple-case and 110 single-case families further localized the defect to the HLA-DQ/DR locus. Environmental factors, particularly drugs such as phenytoin, d-penicillamine, gold, and sulfasalazine are suspected to be triggers for disease expression in individuals with the permissive genetic background.

Most cases of CVID are sporadic or follow an autosomal dominant pattern of inheritance. Patients who lack ICOS, a surface protein on palpable lymph nodes), and serum concentrations of IgG, IgA, IgM, and IgE are far below the 95% confidence limits for appropriate age-and race-matched controls usually with total immunoglobulins <100 mg/dL. Levels of natural antibodies to type A and B red blood cell polysaccharide antigens (isohemagglutinins) and antibodies to antigens given during routine immunizations are abnormally low in this disorder, whereas they are normal in transient hypogammaglobulinemia of infancy. Flow cytometry is an important test to demonstrate the absence of circulating B cells, which will distinguish this disorder from common variable immunodeficiency, the hyper-IgM syndrome and transient hypogammaglobulinemia of infancy.

activated T cells, have an autosomal recessive pattern of inheritance. Nine such patients from 6 families in the Black Forest of Germany have been found to have identical homozygous large genomic deletions of ICOS gene, suggesting a founder effect. Those who have XLP have an X-linked pattern of inheritance and those with autosomally inherited TACI defects may have heterozygous or homozygous mutations.

Despite normal numbers of circulating immunoglobulin-bearing B lymphocytes and the presence of lymphoid cortical follicles, blood B lymphocytes from CVID patients do not differentiate normally into immunoglobulin-producing cells when stimulated with pokeweed mitogen in vitro, even when cocultured with normal T cells. They also have a deficiency of switched memory B cells. B cells from some CVID and some IgA-deficient patients can be stimulated both to switch isotype and to synthesize and secrete some immunoglobulin when stimulated with anti-CD40 and interleukin (IL)-4 or IL-10. T cells and T-cell subsets are usually present in normal percentages, although T-cell function is depressed in some patients.

**Clinical Manifestations**

The serum immunoglobulin and antibody deficiencies in CVID may be as profound as in XLA. Patients with CVID often have autoantibody formation and normal-sized or enlarged tonsils and lymph nodes; ≈25% of patients have splenomegaly. CVID has also been associated with a sprue-like enteropathy with or without nodular follicular lymphoid hyperplasia of the intestine, thymoma, alopecia areata, hemolytic anemia, gastric atrophy, achlorhydria, thrombocytopenia, and pernicious anemia. Lymphoid interstitial pneumonia, intestinal lung disease, pseudolymphoma, B-cell lymphomas, amyloidosis, and noncaseating sarcoid-like granulomas of the lungs, spleen, skin, and liver also occur. There is a 438-fold increase in lymphomas among affected women in the 5th and 6th decades of life. CVID has been reported to resolve transiently or permanently in patients who acquire HIV infection.

Recurrent or chronic infections include pneumonia, sinusitis, otitis media, and diarrhea (bacterial, giardiasis). Repeated pulmonary infections may produce bronchiectasis. Sepsis and meningitis with encapsulated bacteria occur more frequently than in the general population. There is often a delay in the diagnosis of more than 5 yr between the first infections and a definitive diagnosis.

**Selective IgA Deficiency**

An isolated absence or near absence (<10 mg/dL) of serum and secretory IgA is the most common well-defined immunodeficiency disorder, with a disease frequency as high as 0.33% in some populations. This condition can also be and often is associated with ill health.

The basic defect resulting in IgA deficiency is unknown. Phenotypically normal blood B cells are present. IgA deficiency occasionally remits spontaneously or after discontinuation of phenytoin therapy. The occurrence of IgA deficiency in both males and females and in members of successive generations within families suggests autosomal dominant inheritance with variable expressivity. This defect also occurs commonly in pedigrees containing individuals with CVID. Indeed, IgA deficiency may evolve into CVID, and the finding of rare alleles and deletions of MHC class III genes in both conditions suggests that the susceptibility gene common to these 2 conditions may reside in the MHC region on chromosome 6. IgA deficiency is noted in patients treated with the same drugs associated with producing CVID (phenytoin, d-penicillamine, gold, and sulfasalazine), suggesting that environmental factors may trigger this disease in a genetically susceptible person.

**Clinical Manifestations**

Infections occur predominantly in the respiratory, gastrointestinal, and urogenital tracts. Bacterial agents responsible are the same as in other antibody deficiency syndromes. Intestinal giardiasis is common. Children with IgA deficiency vaccinated intranasally with killed poliovirus produced local IgM and IgA antibodies. Serum concentrations of other immunoglobulins are usually normal in patients with selective IgA deficiency, although IgG, (and other) subclass deficiency has been reported, and IgM (usually elevated) may be monomeric.

Patients with IgA deficiency often have IgG antibodies against cow’s milk and ruminant serum proteins. These antiruminant antibodies may cause false-positive results in immunoassays for IgA that use goat (but not rabbit) antisera. IgA deficiency is associated with a celiac-like syndrome, which may or may not respond to a gluten-free diet. The incidence of autoantibodies, autoimmune diseases, and malignancy is increased. Serum antibodies to IgA are reported in as many as 44% of patients with selective IgA deficiency. If these antibodies are of the IgE isotype, they can cause severe or fatal anaphylactic reactions after intravenous administration of blood products containing IgA. Only 5-times washed (in 200-mL volumes) normal donor erythrocytes (frozen blood would have this done routinely), or blood products from other IgA-deficient individuals, should be administered to patients with IgA deficiency. Many intravenous immunoglobulin (IVIG) preparations contain sufficient IgA to cause anaphylactic reactions. Administration of IVIG, which is >99% IgG, is not indicated because most IgA-deficient patients make IgG antibodies normally.

**IgG Subclass Deficiencies**

Some patients have deficiencies of 1 or more of the 4 subclasses of IgG despite normal or elevated total IgG serum concentration. Some
patients with absent or very low concentrations of IgG2 also have IgA deficiency. Other patients with IgG subclass deficiency have gone on to develop CVID, suggesting that the presence of IgG subclass deficiency may be a marker for more generalized immune dysfunction. The biologic significance of the numerous moderate deficiencies of IgG subclasses that have been reported is difficult to assess, particularly because commercial laboratory measurement of IgG subclasses is problematic. IgG subclass measurement is not cost-effective in evaluating immune function in the child with recurrent infection. The more relevant issue is a patient’s capacity to make specific antibodies to protein and polysaccharide antigens, because profound deficiencies of antipolysaccharide antibodies have been noted even in the presence of normal concentrations of IgG. IVIG should not be administered to patients with IgG subclass deficiency unless they are shown to have a deficiency of antibodies to a broad array of antigens.

IMMUNOGLOBULIN HEAVY- AND LIGHT-CHAIN DELETIONS

Some completely asymptomatic individuals have been documented to have a total absence of IgG1, IgG2, IgG3, and/or IgA, as a result of gene deletions. These abnormalities were discovered fortuitously in 16 individuals, 15 of whom had no history of undue susceptibility to infection, and all of whom produced antibodies of all other isotypes in normal quantities. These patients illustrate the importance of assessing specific antibody formation before deciding to initiate IVIG therapy in IgG subclass-deficient patients.

HYPER-IgM SYNDROME

The hyper-IgM syndrome is genetically heterogeneous and characterized by normal or elevated serum IgM levels associated with low or absent IgG, IgA, and IgE serum levels, indicating a defect in the class-switch recombination (CSR) process. Causative mutations have been identified in 2 genes on the X chromosome, the CD40 ligand (hyper-IgM syndrome type 1 [HIGM1]) and NEMO (nuclear factor κB essential modulator, XHM-ED) genes; and 3 genes on autosomal chromosomes, the activation-induced cytidine deaminase (AID) gene (hyper-IgM type 2 [HIGM2]) on chromosome 12, the uracil DNA glycosylase gene (UNG, hyper-IgM type 5 [HIGM5]), on chromosome 12, and the CD40 gene (hyper-IgM type 3 [HIGM3]) on chromosome 20. Distinctive clinical features permit presumptive recognition of the type of mutation in these patients, thereby aiding proper choice of therapy. All such patients should undergo molecular analysis to ascertain the affected gene for purposes of genetic counseling, carrier detection, and decisions regarding definitive therapy.

X-Linked Hyper-IgM Caused By Mutations in the CD40 Ligand: Hyper-IgM Type 1

HIGM1 is caused by mutations in the gene that encodes the CD40 ligand (CD154, CD40L), which is expressed on activated T-helper cells. Boys with this syndrome have very low serum concentrations of IgG and IgA, with a usually normal or sometimes elevated concentration of polyclonal IgM, may or may not have small tonsils, usually have no palpable lymph nodes, and often have profound neutropenia.

Genetics and Pathogenesis

B cells from boys with the CD40 ligand defect are capable of synthesizing not only IgM but also IgA and IgG when cocultured with normal activated T-helper cells, indicating that the B cells are actually normal in this condition and that the defect is in the T cells. The abnormal gene is localized to Xq26, and the gene product, CD154 (CD40L), is the ligand for CD40, which is present on B cells and monocytes. CD154 is upregulated on activated T cells. Mutations in CD154 result in an inability to signal B cells to undergo isotype switching, and thus the B cells produce only IgM. The failure of T cells to interact with B cells through this receptor–ligand pair also causes a failure of upregulation of the B cell and monocyte surface molecules CD80 and CD86 that interact with CD28/CTLA4 on T cells, resulting in failure of “crosstalk” between immune system cells. The failure of interaction of the molecules of those pathways results in a propensity for tolerogenic T-cell signaling and defective recognition of tumor cells. More than 73

AID, Activation-induced cytidine deaminase; BAFF-R, B-cell-activating factor of the tumor necrosis factor family receptor; BLNK, B-cell linker; Btk, Bruton tyrosine kinase; C4, constant region-μ; CD40L, CD40 ligand; CSR, class-switch recombination; CVID, common variable immunodeficiency; ICOS, inducible costimulator; ND, not determined; NEMO, nuclear factor kappa B essential modulator; NF-κB, nuclear factor kappa B, PI3K, phosphatidylinositol 3 kinase; SAP, signaling lymphocyte activation molecule (SLAM)-associated protein; TACI, transmembrane activator, calcium modulator, and cyclophilin ligand interactor; UNG, uracil DNA glycosylase.

distinct point mutations or deletions in the gene encoding CD154 have been identified in 87 unrelated families, giving rise to frame shifts, premature stop codons, and single amino acid substitutions, most of which are clustered in the domain with homology to tumor necrosis factor (TNF), located in the carboxyterminal region.

Clinical Manifestations
Similar to patients with XLA, boys with the CD40 ligand defect become symptomatic during the 1st or 2nd yr of life with recurrent pyogenic infections, including otitis media, sinusitis, pneumonia, and tonsillitis. They have marked susceptibility to P. jiroveci pneumonia, and are frequently profoundly neutropenic. Lymph node histology shows only abortive germinal center formation with severe depletion and phenotypic abnormalities of follicular dendritic cells. These patients have normal numbers of circulating B lymphocytes, but a decreased frequency of CD27+ memory B cells. Circulating T cells are also present in normal number and in vitro responses to mitogens are normal, but there is decreased antigen-specific T-cell function. In a study of patients with the CD40 ligand defect, 23.3% had died at a mean age at death of 11.7 yr. In addition to opportunistic infections such as P. jiroveci pneumonia, there is an increased incidence of extensive verruca vulgaris lesions, Cryptosporidium enteritis, subsequent liver disease, and an increased risk of malignancy. Because of the poor prognosis, the treatment of choice is an HL-A-identical hematopoietic stem cell transplant at an early age. Alternative treatment for this condition is monthly infusion of IVIG. In patients with severe neutropenia, the use of granulocyte colony-stimulating factor has been beneficial.

X-Linked Hyper-IgM Caused By Mutations in the Gene Encoding Nuclear Factor κB Essential Modulator; XHM-ED
This syndrome in males is characterized most often clinically as anhidrotic ectodermal dysplasia with associated immunodeficiency (EDA-ID). The condition results from missense mutations in the IKBKGN gene at position 28q on the X chromosome that encodes NEMO, a regulatory protein required for the activation of the transcription factor NF-κB. Germ line loss-of-function mutations cause the X-linked dominant condition incontinentia pigmenti in females and are lethal in male fetuses. Mutations in the coding region of IKBKGN are associated with EDA-ID. The immunodeficiency is variable, with most patients showing impaired antibody responses to polysaccharide antigens. Some patients with EDA-ID have hyper-IgM. Pharmacologic inhibitors of NF-κB activation have been shown to downregulate CD154 messenger RNA and protein levels, suggesting the mechanism of hyper-IgM in this condition. The hyper-IgM patients with this defect should be easily recognizable because of the presence of ectodermal dysplasia, although there are some patients with this condition who do not have ectodermal dysplasia.

Autosomal Recessive Hyper-IgM Caused By Mutations in the Gene for Activation-Induced Cytidine Deaminase: Hyper-IgM Type 2
An autosomal recessive form of hyper-IgM syndrome is caused by mutations in the gene for AID.

Genetics and Pathogenesis
Patients with autosomal recessive hyper-IgM usually have normal numbers of circulating B lymphocytes, but, in contrast to patients with the CD40 ligand defect, B cells from these patients are not able to switch from IgM-secreting to IgG-, IgA-, or IgE-secreting cells, even when cocultured with normal T cells or with monoclonal antibodies to CD40 and a variety of cytokines. When their B cells are cultured in vitro, they spontaneously secrete large amounts of IgM, but this is not further augmented by the addition of cytokines. Thus, in these patients, there is truly an intrinsic B-cell abnormality. The defect in many such patients has been identified as due to mutations in a gene on chromosome 12p13 that encodes AID. AID is a single-stranded DNA deaminase required for somatic hypermutation (SHM) and class-switch recombination (CSR) of immunoglobulin genes. Histologic examination of the enlarged lymph nodes reveals the presence of giant germinal centers (5-10 times larger than normal) filled with highly proliferating B cells. Proliferating B cells coexpress IgM, IgD, and CD38, a phenotype previously described for a small B-cell subset corresponding to germinal center founder cells. These cells are thought to correspond to a transitional stage between follicular mantle and germinal center B cells, at the onset of somatic mutation of the Ig variable region gene and antigen-driven selection. Deficiency of AID results in impaired terminal differentiation of B cells, a failure of CSR, and lack of immunoglobulin gene SHM. They have a normal frequency of CD27+ memory B cells.

Clinical Manifestations
Concentrations of serum IgG, IgA, and IgE are very low in AID deficiency. In contrast to the CD40 ligand defect, however, the serum IgM concentration in patients with AID deficiency is usually markedly elevated and polyclonal. Patients with this form of hyper-IgM have lymphoid hyperplasia, are generally older at age at onset, do not have susceptibility to P. jiroveci pneumonia, often do have isohemagglutinins, and are much less likely to have neutropenia unless it occurs on an autoimmune basis. They have a tendency, however, to develop autoimmune and inflammatory disorders including diabetes mellitus, polyarthritus, autoimmune hepatitis, hemolytic anemia, immune thrombocytopenia, Crohn disease, and chronic uveitis. With early diagnosis and monthly infusions of IVIG, as well as good management of infections with antibiotics, patients with AID mutations generally have a more benign course than do boys with the CD40 ligand defect.

Autosomal Recessive Hyper-IgM Caused By Mutations in the Gene for Uracil DNA Glycosylase; Hyper-IgM Type 5
Genetics and Pathogenesis
AID deaminates cytosine into uracil in targeted DNA, which is followed by uracil removal by Ung. Severely impaired CSR was found in 3 hyper-IgM patients reported to have Ung deficiency. Their clinical characteristics were similar to those with AID deficiency, with increased susceptibility to bacterial infections and lymphoid hyperplasia. The patients had a markedly elevated serum IgM and profoundly decreased serum IgG and IgA concentrations. Their B cells had an intrinsic defect in CSR when stimulated with anti-CD40 and IL-4 and constitutively produced high quantities of IgM. They had only a partial defect in SHM, however, and they have a normal frequency of CD27+ memory B cells.

Autosomal Recessive Hyper-IgM Caused By Mutations in CD40: Hyper-IgM Type 3
Five patients with autosomal recessive hyper-IgM from 4 unrelated families failed to express CD40 on their B-cell surfaces and were found to have mutations in the CD40 gene. Clinical manifestations included recurrent sinopulmonary infections, P. jiroveci pneumonia and Cryptosporidium parvum infections. The patients had very low levels of IgG and IgA and normal or high levels of IgM. More recently, 2 patients were identified with such mutations who did express the CD40 protein on their B cells and monocytes, so mutation analysis was required to make the diagnosis.

Genetics and Pathogenesis
CD40 is a type 1 integral membrane glycoprotein encoded by a gene on chromosome 20 and belonging to the TNF and nerve growth factor receptor superfamily. It is expressed on B cells, macrophages, dendritic cells, and a few other types of cells. Mutations in the CD40 gene cause an autosomal recessive form of hyper-IgM syndrome that is clinically indistinguishable from HIGM1, resulting from the X-linked CD40 ligand (CD154) defect. In contrast to the CD40 ligand defect, however, the B cells in the autosomal recessive condition are intrinsically abnormal and cannot isotype switch. The T cells are normal except to the extent that they cannot cause upregulation of CD80 and CD86 on B cells and macrophages to interact with CD28/CTLA4 on T cells.
Hyper-IgM Type 4
The defective gene in a 4th autosomal recessive form of hyper-IgM syndrome has not yet been identified, but appears to be in a gene downstream of AID. These patients all have defective CSR with preserved SHM.

X-LINKED LYMPHOPROLIFERATIVE DISEASE
XLP disease, also referred to as Duncan disease after the original kindred in which it was described, is an X-linked recessive trait characterized by an inadequate immune response to infection with Epstein-Barr virus (EBV).

Genetics and Pathogenesis
The defective gene in XLP was localized to Xq25, cloned, and the gene product was initially named SAP (for SLAM-associated protein), but is now known officially as SH2D1A. SLAM (signaling lymphocyte activation molecule) is an adhesion molecule that is upregulated on both T and B cells with infection and other stimulation. SH2D1A is highly expressed in thymocytes and peripheral blood T and NK cells, with a prevalent expression on T-helper type 1 cells. Its presence on B lymphocytes is unclear. Thus, although antibody deficiency is frequently present, this is really a T- and natural killer (NK)-cell defect. SH2D1A competes with SHP-2 for binding to SLAM and, as such, is a regulatory molecule. In XLP patients, the absence of SH2D1A can lead to an uncontrolled cytotoxic T-cell immune response to EBV. The SH2D1A protein associates permissively with 2B4 on NK cells; thus, selective impairment of 2B4-mediated NK-cell activation also contributes to the immunopathology of XLP.

Clinical Manifestations
AFFECTED MALES
Affected males are usually healthy until they acquire EBV infection. The mean age of presentation is <5 yr. There are 3 major clinical phenotypes: (1) fulminant, often fatal, infectious mononucleosis (50% of cases); (2) lymphomas, predominantly involving B-lineage cells (25%); and (3) acquired hypogammaglobulinemia (25%). There is a marked impairment in production of antibodies to the EBV nuclear antigen, whereas titers of antibodies to the viral capsid antigen have ranged from absent to markedly elevated. XLP has an unfavorable prognosis; 70% of affected boys die by age 10 yr. Only 2 XLP patients are known to have survived beyond 40 yr of age. Unless there is a family history of XLP, diagnosis prior to the onset of complications is difficult because affected individuals are asymptomatic initially. Using mutation analysis, it is possible to identify affected males within identified kindreds before they develop primary EBV infection. Approximately half of the few patients with XLP given HLA-identical related or unrelated stem cell transplants are surviving without signs of the disease.

Two pedigrees have been reported in which boys in one arm of each pedigree were diagnosed with CVID, whereas those in the other arms had fulminant infectious mononucleosis. The family members with CVID never gave a history of infectious mononucleosis. All affected members of each pedigree had the same distinct SH2D1A mutation, however, despite the different clinical phenotypes. Because the SH2D1A mutation was the same but the phenotype varied in these families, XLP should be considered in all males with a diagnosis of CVID, particularly if there is more than one male family member with this phenotype.

Bibliography

In general, patients with defects in T-cell function have infections or other clinical problems that are more severe than in patients with antibody deficiency disorders (see Table 122-4). The defective gene products for some primary T-cell diseases are identified (Table 125-1). These individuals rarely survive beyond infancy or childhood. Transplantation of thymic tissue, or of major histocompatibility complex–compatible sibling or haploidentical (half-matched) parental hematopoietic stem cells, is the treatment of choice for patients with primary T-cell defects (see Chapter 135).

**THYMIC HYPOPLASIA (DIGEORGE SYNDROME)**

Thymic hypoplasia results from dysmorphogenesis of the 3rd and 4th pharyngeal pouches during early embryogenesis, leading to hypoplasia or aplasia of the thymus and parathyroid glands. Other structures forming at the same age are also frequently affected, resulting in anomalies of the great vessels (right-sided aortic arch), esophageal atresia, bifid uvula, congenital heart disease (conotruncal, atrial, and ventricular septal defects), a short philtrum of the upper lip, hypertelorism, an ankyloblepharon, microphthalmia, and hypoplasia of the external ears. Variable hypoplasia of the thymus and parathyroid glands defines partial DiGeorge syndrome, which is more frequent than total aplasia; aplasia is present in <1% of patients with DiGeorge syndrome and defines complete DiGeorge syndrome. Slightly less than half of patients with complete DiGeorge syndrome have CHARGE association (coloboma, heart defect, choanal atresia, growth or developmental retardation, genital hypoplasia, and ear anomalies including deafness). Mutations in the chromodomain helicase DNA binding protein 7 (CHD7) gene on chromosome 8q12.2 are found in approximately 60-65% of individuals with CHARGE syndrome. Concentrations of serum immunoglobulins in DiGeorge syndrome are usually normal, but immunoglobulin (Ig) A may be diminished and IgE elevated. Other laboratory findings vary depending on the degree of thymic dysfunction.

AIRE, Autoimmune regulator; APECED, autoimmune polyendocrinopathy-candidiasis ectodermal dysplasia; Ig, immunoglobulin; ITK, IL-2-inducible tyrosine kinase deficiency; MST1, macrophage-stimulating factor 1; NKT, natural killer T; RhoH, Ras homology family member H; STK4, serine threonine kinase 4; TCR, T-cell receptor; TRAC, T-cell receptor α chain constant region; ZAP-70, zeta-associated protein 70.
Absolute lymphocyte counts are usually only moderately low for age. The CD3 T-cell counts are variably decreased in number, corresponding to the degree of thymic hypoplasia, resulting in an increased percentage of B cells. Lymphocyte responses to mitogen stimulation are absent, reduced, or normal, depending on the degree of thymic deficiency. Thymic tissue, when found, contains Hassall corpuscles, a normal density of thymocytes, and corticomedullary distinction. Lymphoid follicles are usually present, but lymph node paracortical areas and thymus-dependent regions of the spleen show variable degrees of depletion.

**Clinical Manifestations**

Children with partial thymic hypoplasia may have little trouble with infections and grow normally. Patients with complete DiGeorge syndrome resemble patients with severe combined immunodeficiency in their susceptibility to infections with low-grade or opportunistic pathogens, including fungi, viruses, and *Pneumocystis jiroveci*, and to graft-versus-host disease from nonirradiated blood transfusions. Patients with complete DiGeorge syndrome can develop an atypical phenotype in which oligoclonal T-cell populations appear in the blood associated with rash and lymphadenopathy. These atypical patients appear phenotypically to be similar to patients with Omenn syndrome or maternal T lymphocyte engraftment.

It is critical to confirm the diagnosis of complete DiGeorge syndrome in a timely manner because this disease is fatal without treatment. A T-cell count should be obtained on all infants born with primary hypoparathyroidism, CHARGE syndrome, truncus arteriosus, and interrupted aortic arch type B. If a patient has findings consistent with DiGeorge syndrome with or without a rash and lymphadenopathy, the patient should be referred to an immunologist for evaluation.

**Treatment**

The immune deficiency in the complete DiGeorge syndrome is correctable by cultured unrelated thymic tissue transplants. Some have been given nonirradiated unfractionated bone marrow or peripheral blood transplants from an human leukocyte antigen–identical sibling with subsequent improved immune function because of adoptively transferred donor immunity; however, they have no way of renewing T-cell production because they have no thymus.

**DEFECTIVE EXPRESSION OF THE T-CELL RECEPTOR–CD3 COMPLEX**

The first type of this disorder was found in 2 brothers in a Spanish family. The proband presented with severe infections and died at 31 mo of age with autoimmune hemolytic anemia and viral pneumonia. His lymphocytes had responded poorly to mitogens and to anti-CD3 in vitro, and could not be stimulated to develop cytotoxic T cells. His antibody responses to protein antigens had been normal, indicating normal T-helper cell function. His 12 yr old brother was healthy but had almost no CD3-bearing T cells and had IgG2 deficiency similar to his sibling. The defect in this family was caused by mutations in the gene encoding the CD3γ chain (Fig. 125-1).

The second type of this disorder was diagnosed in a 4 yr old French boy who had recurrent *Haemophilus influenzae* pneumonia and otitis media in early life but was later healthy. He had a partial defect in expression of T-cell receptor–CD3 complex, and thus the percentage of CD3 cells was about half-normal, but the level of expression was markedly decreased. The defect was caused by 2 independent CD3ε gene mutations, leading to defective CD3ε chain synthesis. There was a splice site mutation on one allele that did not totally abrogate the normal intron 7 splicing, resulting in partial expression of CD3 on the T cells. Thus, this mutation did not result in failure of T-cell development, whereas mutations in the portions of the gene that encode the extracellular component of CD3ε result in a profound deficiency of circulating mature CD3 T cells.

Two additional unrelated patients from Pakistan were discovered to lack T-cell receptor (TCR)-αβ-positive T cells and were found to have mutations in the TCR α-chain constant (TRAC) gene. Clinically they
had increased susceptibility to infections, autoimmunity and profound T-cell dysfunction but normal antibody responses. All of their T cells contained TCR gamma delta receptors.

**T-Cell Activation Defects**

T-cell activation defects are characterized by the presence of normal or elevated numbers of blood T cells that appear phenotypically normal but fail to proliferate or produce cytokines normally in response to stimulation with mitogens, antigens, or other signals delivered to the TCR, owing to defective signal transduction from the TCR to intracellular metabolic pathways (see Fig. 125-1). These patients have problems similar to those of other T-cell-deficient individuals, and some with severe T-cell activation defects may clinically resemble severe combined immunodeficiency patients. At least 8 new forms of T-cell activation defects have been discovered. The description of only a few of these conditions is included here (see Table 125-1) and DOCK8 deficiency is discussed in Chapter 126.

**CD8 Lymphocytopenia Caused by Mutations in the Gene Encoding Zeta-Associated Protein 70**

Patients with this T-cell activation defect present during infancy with severe, recurrent, and often fatal infections. The majority of cases are reported among Mennonites. These patients have normal or elevated numbers of blood B cells and low to elevated serum immunoglobulin concentrations. Their blood lymphocytes exhibit normal expression of the T-cell surface antigens CD3 and CD4, but CD8 cells are almost totally absent. These cells fail to respond normally to mitogens or to allogeneic cells in vitro or to generate cytotoxic T lymphocytes. Natural killer (NK) cell activity is normal. The thymus of 1 patient exhibited normal architecture with normal numbers of CD4:CD8 double-positive thymocytes, but an absence of CD8 single-positive thymocytes. This condition is caused by mutations in the gene encoding zeta-associated protein 70 (ZAP-70), a non-src family protein tyrosine kinase important in T-cell signaling that is localized to chromosome 2q12 (see Fig. 125-1). The normal number of CD4:CD8 double-positive T cells results because the thymocytes can use the other member of the same tyrosine kinase family, Syk, to facilitate positive selection. Syk is present at 4-fold higher levels in thymocytes than in peripheral T cells, possibly accounting for the lack of normal responses by the CD4 blood T cells.

Another condition that can result in CD8 deficiency is a mutation in the gene that encodes CD8α. There is a deficiency of cytotoxic T cells in that condition, but the functional immune defect is mild compared to that of ZAP-70 deficiency.

**T-Cell Defects Characterized By Epstein-Barr Virus Lymphoproliferation/Lymphoma**

In addition to the X-linked lymphoproliferative and X-linked inhibitor of apoptosis protein syndromes and CD272 deficiency characterized primarily as antibody deficiencies (see Chapter 124), there are at least 4 additional primarily T-cell defects that predispose to Epstein-Barr virus (EBV) infections or lymphomas. These include Ras homology family member H (RhoH) deficiency, macrophage-stimulating 1 (MST1)/serine threonine kinase 4 (STK4) deficiency, interleukin (IL)-2–inducible tyrosine kinase (ITK) deficiency and Coronin-1A deficiency (see Table 125-1).

**RhoH Deficiency**

Two siblings who had a homozygous nonsense mutation in the RhoH gene had persistent cutaneous human papillomavirus infections and the older sibling had Burkitt lymphoma. RhoH plays an important role in T-cell activation. Following stimulation of the TCR, RhoH becomes tyrosine phosphorylated and mediates recruitment of ZAP-70 and LCK to the TCR/linker of activation in T cells (LAT) signalosome (see Fig. 125-1). Immunologic findings in the 2 patients included a reduced number of naïve CD4+ T cells and recent thymic emigrants, restricted T-cell diversity and impaired responsiveness of the cells to anti-CD3.

**MST1/STK4 Deficiency**

Autosomal recessive MST1/STK4 deficiency is associated with recurrent bacterial and viral infections, candidiasis and autoimmunity. The viral infections include warts, molluscum contagiosum, and EBV lymphoproliferative disease. Congenital heart disease and moderate neutropenia have also been reported. Immunologically, there is a severe reduction in naïve T cells, a near absence of recent thymic emigrants, oligoclonal T cells and increased apoptosis of T cells. Thus, MST1/STK4 plays a major role in T-cell development, survival, and migration.

**ITK Deficiency**

Several patients with EBV lymphoproliferative disease have been described who had mutations in the ITK gene. In addition, some also had P. jiroveci pneumonia, candidiasis, and BK polyoma infection. The immunologic abnormalities described included marked lymphopenia, a predominance of activated T cells, an absence of NK T cells, and poor T-cell responses to mitogens, antigens and anti-CD3. ITK is a Tec nonreceptor tyrosine kinase expressed in T lymphocytes. The ITK pleckstrin homology domain binds to phosphatidylinositol monophosphates and this binding permits ITK recruitment to the T cell membrane where, upon TCR crosslinking, ITK increases phosphatidylcholine (PLCγ) 1 activation and calcium influx.

**Coronin-1a Deficiency**

Three siblings from a consanguineous family presented with EBV-associated B-cell lymphoproliferation at an early age (12, 7, and 14 mo) and profound naïve T-cell lymphopenia. In addition, there was impaired development of a diverse T-cell repertoire and near absent invariant NK T cells. They were discovered to have a missense mutation in the gene encoding Coronin-1A that abrogated protein expression. Coronin-1A is a member of a family of proteins that bind F-actin and the Arp2/3 complex; it has an important role in cytoskeletal organization.

**LCK Deficiency**

A female infant presented at age 15 mo with protracted diarrhea, failure to thrive and recurrent respiratory tract infections. She developed recurring fevers, multiple nodular skin lesions and inflammation of the interphalangeal joints as well as retinal vasculitis and pyleusritis. At age 29 mo, she developed a normocytic aregenerative anemia and peripheral thrombocytopenia with antiplatelet autoantibodies. She died from venoocclusive disease shortly after a chemoablated bone marrow transplant. Immunologic investigation revealed CD4 T lymphopenia and low levels of CD4 and CD8 expression on the T-cell surfaces. The T cells present had an oligoclonal T-cell repertoire and exhibited a profound TCR signaling defect. She was found to have a homozygous missense mutation of the LCK gene.

Very closely related to this defect is a deficiency of uncoordinated 119 (UNC119), which is a chaperone involved in LCK-mediated signaling. Through LCK, UNC119 regulates T-cell proliferation, differentiation into T effector cells and immunologic synapse formation. A heterozygous dominant-negative missense mutation of the UNC119 gene was reported in a 32 yr old female with idiopathic CD4 T lymphopenia who had a history of recurrent respiratory infections, shingles, oral herpes infections and persistent fungal infections of the skin and nails. Both LCK deficiency and UNC119 deficiency should be considered when there is idiopathic CD4 T lymphopenia.

**CHRONIC MUCOCUTANEOUS CANDIDIASIS**

Chronic mucocutaneous candidiasis is a syndrome characterized by impaired immune responsiveness to *Candida*. Some of the known immunodeficiencies that have this complication as a prominent feature include autoimmune polyclonocytopenia syndrome type 1 (APS1, or autoimmune polyclonocytopenia-candidiasis-ectodermal dystrophy [APSCED], described below), homozygous caspase recruitment domain-containing protein 9 (CARD9) mutations, both types of hyperimmunoglobulin E syndromes (see Chapter 126), an autosomal recessive deficiency in the IL-17 receptor A (IL-17RA) chain, and an...
autosomal dominant deficiency of STAT1 and of the cytokine IL-17F. IL-17RA deficiency is complete, abolishing cellular responses to IL-17A and IL-17F homo- and heterodimers. By contrast, IL-17F deficiency is partial, with mutant IL-17F-containing homo- and heterodimers displaying impaired, but not abolished, activity.

Although the underlying immune disorders are varied, the clinical presentation of chronic mucocutaneous candidiasis is usually similar. Symptoms can begin in the 1st mo of life or as late as the 2nd decade of life. The disorder is characterized by chronic and severe Candida skin and mucous membrane infections. Patients rarely develop systemic Candida disease except as noted below. Topical antifungal therapy can provide limited improvement early in the course of the disease, but systemic courses of azoles are usually necessary. The infection usually responds temporarily to treatment but is not eradicated and recurs. Patients with CARD9 gene mutations have a more severe fungal susceptibility than typical chronic mucocutaneous candidiasis patients. Two described patients with CARD9 gene mutations had fungal sepsis in addition to chronic mucocutaneous candidiasis; deep tissue dermatophyte infections were also present.

**AUTOIMMUNE POLYENDOCRINOPATHY-CANDIDIASIS ECTODERMAL DYSPLASIA**

Patients with this syndrome present with chronic mucocutaneous candidiasis and autoimmune polyendocrinopathy, usually producing hypoparathyroidism and Addison disease. Additional features include hypogonadism, chronic active hepatitis, alopecia, vitiligo, pernicious anemia, enamel hypoplasia, type 1 diabetes, and Sjögren syndrome. APECED, or APS1, is caused by a mutation in the autoimmune regulator (AIRE) gene (see Table 125-1). The gene product, AIRE, is expressed at high levels in purified human thymic medullary stromal cells and is thought to regulate the cell surface expression of tissue-specific proteins such as insulin and thyroglobulin. Expression of these self-proteins allows for the negative selection of autoreactive T cells during their development. Failure of negative selection results in organ-specific autoimmune destruction. The overall significance of AIRE in the establishment and maintenance of T-cell self-tolerance is not well understood.

*Bibliography is available at Expert Consult.*
Patients with combined antibody and cellular defects have severe, frequently opportunistic infections that lead to death in infancy or childhood unless they are provided hematopoietic stem cell transplantation early in life. These are thought to be rare defects, although the true incidences are unknown because until recently there had been no newborn screening for any of these defects. It is possible that many affected children died of infection during infancy without being diagnosed. The causative mutated genes for many combined immunodeficiencies have been identified (Table 126-1). Because life-threatening infections may occur early in infancy, the U.S. Secretary of Health and Human Services recommends that routine screening for severe combined immunodeficiency (SCID) be included in state newborn screening testing. Live, vaccine-derived rotaviral infections have already occurred during the 1st few mo of life in SCID infants, so very early knowledge of this diagnosis could prevent such vaccine-acquired infections. In addition, early identification and subsequent bone marrow transplantation before infections develop result in a very high (92%) survival rate.

### 126.1 Severe Combined Immunodeficiency

Rebecca H. Buckley

The syndromes of SCID are caused by diverse genetic mutations that lead to absence of all adaptive immune function and, in some, a lack of B cells and natural killer (NK) cells. Patients with this group of disorders have the most severe immunodeficiency.

#### PATHOGENESIS

SCID results from mutations in any 1 of at least 13 known genes that encode components of the immune system crucial for lymphoid cell development (Table 126-2). All patients with SCID have very small thymuses (<1 g) that usually fail to descend from the neck, contain no thymocytes, and lack corticomedullary distinction or Hassall corpuscles. The thymic epithelium appears histologically normal. Both the follicular and paracortical areas of the spleen are depleted of lymphocytes. Lymph nodes, tonsils, adenoids, and Peyer patches are absent or extremely underdeveloped.

#### CLINICAL MANIFESTATIONS

Affected infants present within the 1st few mo of life with recurrent or persistent diarrhea, pneumonia, otitis media, sepsis, and cutaneous infections. Growth may appear normal initially, but extreme wasting usually ensues after diarrhea and infections begin. Persistent infections with opportunistic organisms including *Candida albicans*, *Pneumocystis jiroveci*, parainfluenza 3 virus, adenovirus, respiratory syncytial virus, rotavirus vaccine virus, cytomegalovirus, Epstein-Barr virus (EBV), varicella-zoster virus, measles virus, MMR-V (measles, mumps, rubella, varicella) vaccine virus, or bacillus Calmette-Guérin (BCG) lead to death. Affected infants also lack the ability to reject foreign tissue and are therefore at risk for severe or fatal graft-versus-host disease (GVHD) from T lymphocytes in nonirradiated blood products or in allogeneic stem cell transplants or less severe GVHD from maternal immunocompetent T cells that crossed the placenta while the infant was in utero.

Because all molecular types of SCID lack T cells, the profound T-cell lymphopenia can be detected on dried blood spots routinely collected from heel sticks shortly after birth for the purpose of newborn screening by assaying for the presence of T-cell receptor recombination excision circles by real time polymerase chain reaction. T-cell receptor recombination excision circles are absent or extremely low in SCID infants. These infants also have an absence of lymphocyte proliferative responses to mitogens, antigens, and allogeneic cells in vitro. Patients with adenosine deaminase (ADA) deficiency have the lowest absolute lymphocyte counts, usually <500/mm³, but infants with all molecular types of SCID are lymphopenic because they lack T cells (normally accounting for 70% of circulating lymphocytes). Serum immunoglobulin concentrations are low or absent, and no antibodies are formed after immunizations. Analyses of lymphocyte populations and subpopulations demonstrate distinctive phenotypes for the various genetic forms of SCID (see Table 126-2). T cells are extremely low or absent in all types; when detected, in most cases they are transplacentally derived maternal T cells.

#### TREATMENT

SCID is a true pediatric emergency. Unless immunologic reconstitution is achieved through stem cell transplantation or gene therapy, death usually occurs during the 1st yr of life and almost invariably before 2 yr of age. If diagnosed at birth or within the 1st 3.5 mo of life, >92% of cases can be treated successfully with human leukocyte antigen (HLA)-identical or T-cell–depleted haploidentical (half-matched) parental hematopoietic stem cell transplantation without the need for pretransplant chemoablation or posttransplant GVHD prophylaxis. ADA-deficient SCID and X-linked SCID have been treated
success with somatic gene therapy; although serious adverse events occurred in the case of X-linked SCID. ADA-deficient SCID can also be treated with repeated injections of polyethylene glycol modified bovine ADA (PEG-ADA), although the immune reconstitution achieved is not nearly as good as with stem cell or gene therapy. PEG-ADA should not be started if nonablative stem cell transplantation is contemplated because it will enable the infant to reject the graft.

X-LINKED SEVERE COMBINED IMMUNODEFICIENCY CAUSED BY MUTATIONS IN THE GENE ENCODING THE COMMON CYTOKINE RECEPTOR γ CHAIN

X-linked SCID (X-SCID) is the most common form of SCID in the United States, accounting for 47% of cases (Fig. 126-1). Clinically, immunologically, and histopathologically, affected individuals appear...

similar to those with other forms of SCID except for having uniformly low percentages of T and NK cells and an elevated percentage of B cells (T−, B+, NK−), a characteristic feature shared only with Janus kinase 3 (Jak3)–deficient SCID. The abnormal gene in X-SCID was mapped to Xq13, cloned, and found to encode the common γc chain (γc) for several cytokine receptors, including interleukin (IL)-2, IL-4, IL-7, IL-9, IL-15, and IL-21. The shared γc functions both to increase the affinity of the receptor for the respective cytokine and to enable the receptors to mediate intracellular signaling. Incapacitation of the receptors for all of these developmentally crucial cytokines by genetic mutations in γc provides an explanation for the severity of the immunodeficiency in X-SCID. In the 1st 136 patients studied, 95 distinct mutations spanning all 8 IL-2RG exons were identified, most of them consisting of small changes at the level of 1 to a few nucleotides. These mutations resulted in abnormal γc chains in two-thirds of the cases and absent γc protein in the remainder. Carriers can be detected by demonstrating the deleterious mutation in their lymphocytes. Unless donor B or NK cells develop, patients with X-SCID lack B- and NK-cell function after bone marrow transplantation because the abnormal γc persists in those host cells, despite excellent reconstitution of T-cell function by donor-derived T cells.

**AUTOSOMAL RECESSIVE SEVERE COMBINED IMMUNODEFICIENCY**

This pattern of inheritance of SCID is less common in the United States than in other countries. Mutated genes on autosomal chromosomes have been identified in 12 forms of SCID: ADA deficiency; Jak3 deficiency; IL-7 receptor α chain (IL-7Rα) deficiency; recombination-activating gene 1 or 2 (RAG1 or RAG2) deficiency; Artemis deficiency; ligase 4 deficiency; DNA–protein kinase catalytic subunit (DNA-PKcs) deficiency; CD38, CD3ε, CD3ζ deficiency; and CD45 deficiency (see Fig. 126-1).

**Adenosine Deaminase Deficiency**

An absence of the enzyme ADA is observed in approximately 15% of patients, the second most common form of SCID, resulting from various point and deletional mutations in the ADA gene on chromosome 20q13.3. Marked accumulations of adenosine, 2′-deoxyadenosine, and 2′-O-methyladenosine lead directly or indirectly to T-cell apoptosis, which causes the immunodeficiency. ADA-deficient patients usually have a much more profound lymphopenia than do infants with other types of SCID, with mean absolute lymphocyte counts of <500/mm³; the absolute numbers of T, B, and NK cells are very low. NK function is normal. After T-cell function is conferred by hematopoietic stem cell transplantation without pretransplant chemotherapy, there is generally excellent B-cell function despite the fact that the B cells are of host origin. This is because ADA deficiency affects primarily T-cell function. Milder forms of ADA deficiency have led to delayed diagnosis of immunodeficiency, even to adulthood. Other distinguishing features of ADA-deficient SCID include the presence of rib cage abnormalities similar to a rachitic rosary and numerous skeletal abnormalities of chondroosseous dysplasia, which occur predominantly at the costochondral junctions, at the apophyses of the iliac bones, and in the vertebral bodies where a “bone-in-bone” effect is observed.
As with other types of SCID, ADA deficiency can be cured by HLA-identical or haploidentical T-cell–depended stem cell transplantation without the need for pre- or posttransplant chemotherapy; this remains the treatment of choice. Enzyme replacement therapy should not be initiated if stem cell transplantation is possible because it confers graft-rejection capability. Enzyme replacement provides protective immunity but over time there is a decline of lymphocyte counts and proliferative responses. A number of infants with ADA deficiency have become successfully immune reconstituted by gene therapy in Italy, Great Britain and the United States; in all cases, PEG-ADA was withheld. Spontaneous reversion to normal of a mutation in the ADA gene has also been reported.

**Jak3 Deficiency**

Patients with this autosomal recessive defect resemble all other types of SCID patients clinically. They have a lymphocyte phenotype similar only to that of patients with X-SCID, with an elevated percentage of B cells and very low or no T and NK cells. Because Jak3 is the only signaling molecule known to be associated with γc, it was a candidate gene for mutations leading to autosomal recessive SCID. Jak3 deficiency accounts for 6% of SCID cases. Even after successful T-cell reconstitution by transplantation of haploidentical stem cells, patients with Jak3-deficient SCID fail to develop NK cells or normal B-cell function owing to the defective function of those host cells that bear abnormal cytokine receptors that share γc.

**IL-7Rα Deficiency**

Patients with IL-7Rα–deficient SCID have a distinctive lymphocyte phenotype in that, although lacking T cells, they have normal or elevated numbers of both B and NK cells (T−, B+, NK+). This is the third most common form of SCID, accounting for 12% of cases in the United States (see Fig. 126-1). In contrast to patients with γc- and Jak3-deficient SCID, the immunologic defect in these patients is completely correctable by T-cell reconstitution alone, because the host B and NK cells appear to be normal.

**RAG1 or RAG2 Deficiencies**

Infants with these causes of SCID have a different lymphocyte phenotype from those of patients with SCID caused by γc, Jak3, IL-7Rα, or ADA deficiencies in that they lack both B and T lymphocytes and have primarily NK cells in their circulation (T−, B−, NK+). This suggested a problem with their antigen receptor genes, which led to the discovery of mutations in RAG1 or RAG2. Such mutations result in a functional inability to form antigen receptors through genetic recombination.

**Ommen syndrome** is an autosomal recessive syndrome characterized by profound susceptibility to infection and by clonal T-cell infiltration of skin, intestines, liver, and spleen leading to an exfoliative erythroderma, lymphadenopathy, hepatosplenomegaly, and intractable diarrhea. Mutations in the RAG1 and RAG2, as well as rarely in other SCID-causing mutated genes, have been found in patients with this condition. These infants have persistent leukocytosis with marked eosinophilia and lymphocytosis; elevated serum immunoglobulin (Ig) E; low IgG, IgA, and IgM; and low or absent B cells. There is dominance of clonal T-helper (Th)2-like cells, with severely impaired T-cell function as the result of the restricted heterogeneity of the host T-cell repertoire.

**Artémis Deficiency**

Another cause of SCID is a deficiency of a novel V(D)J (variable, diversity, joining) recombination/DNA repair factor, named Artémis, that belongs to the metallo-β-lactamase superfamily, which is encoded on chromosome 10p by a gene named DCLRE1C. Deficiency of Artémis results in an inability to repair DNA after double-stranded cuts by the RAG1 or RAG2 gene products in rearranging antigen receptor genes from their germline configuration. Similar to RAG1- and RAG2-deficient SCID, this defect results in failure to develop T and B cells and is, therefore, another form of T−, B−, NK+ SCID, which is called *Athabascan SCID*. There is increased radiation sensitivity of both skin fibroblasts and bone marrow cells of those affected with this type of SCID as well as with DNA-PKcs and ligase 4 deficiencies.

**CD45 Deficiency**

Another molecular defect causing SCID is a mutation in the gene encoding the common leukocyte surface protein CD45. This hematopoietic cell–specific transmembrane protein tyrosine phosphatase functions to regulate src kinases required for T- and B-cell antigen receptor signal transduction. Three examples of this have been reported. One was found to have a large deletion on 1 CD45 allele and a point mutation causing an alteration of the intervening sequence 13 donor splice site on the other allele. The author has evaluated and treated a third case that was caused by uniparental disomy of chromosome 1 with an inactivating mutation in the gene encoding CD45.

**CD3δ, CD3ε, and CD3ζ Deficiencies**

Other causes of autosomal recessive SCID are deficiencies of components of the T-cell receptor (CD3δ, CD3ε, and CD3ζ chains). Mutations in the portions of these genes that encode the extracellular components of the proteins result in a profound deficiency of circulating mature CD3 T cells. Thus, CD3δ, CD3ε, and CD3ζ appear to be essential for intrathymic development of T cells. Because only T-cell development is affected in these defects, both B and NK cells are normal. Thus, the lymphocyte phenotype resembles that of SCID infants with IL-7Rα chain deficiency (T−B+NK+).

**RETICULAR DYSGENESIS**

Reticular dysgenesis was first described in identical twin boys who exhibited a total lack of both lymphocytes and granulocytes in their peripheral blood and bone marrow. The thymus glands weigh <1 g, have no Hassall corpuscles, and have few or no thymocytes. Reticular dysgenesis is considered a variant of SCID. The molecular basis of this autosomal recessive disorder is caused by mutations in the gene encoding adenylyl kinase 2. The condition is fatal without definitive therapy and the treatment of choice is a fully myeloablative matched sibling bone marrow transplant. However, such transplants have been successful only in 7 of 17 evaluable patients so transplanted.
Combined immunodeficiency (CID) is distinguished from SCID by the presence of low but not absent T-cell function. Similar to SCID, CID is a syndrome of diverse genetic causes (see Table 126-1). Patients with CID have recurrent or chronic pulmonary infections, failure to thrive, oral or cutaneous candidiasis, chronic diarrhea, recurrent skin infections, Gram-negative bacterial sepsis, urinary tract infections, and severe varicella in infancy. Although they usually survive longer than infants with SCID, they fail to thrive and die early in life. Neutropenia and eosinophilia are common. Serum immunoglobulins may be normal or elevated for all classes, but selective IgA deficiency, marked elevation of IgE, and elevated IgD levels occur in some cases. Although antibody-forming capacity is impaired in most patients, it is not absent.

Studies of cellular immune function show lymphopenia, profound deficiencies of T cells, and extremely low but not absent lymphocyte proliferative responses to mitogens, antigens, and allogeneic cells in vitro. Peripheral lymphoid tissues demonstrate paraarcortical lymphocyte depletion. The thymus is very small, with a paucity of thymocytes and usually no Hassall corpuscles. An autosomal recessive pattern of inheritance is common.

**PURINE NUCLEOSIDE PHOSPHORYLASE DEFICIENCY**

More than 40 patients with CID have been found to have purine nucleoside phosphorylase deficiency. Point mutations identified in the purine nucleoside phosphorylase gene on chromosome 14q13.1 account for these deficiencies. In contrast to ADA deficiency, no characteristic physical or skeletal abnormalities have been noted, but serum and urinary uric acid are usually markedly deficient. Deaths result from generalized vaccinia, varicella, lymphosarcoma, or GVHD mediated by allogeneic T cells in nonirradiated blood or bone marrow. Two-thirds of patients have neurologic abnormalities, one-third of patients have autoimmune diseases, and some have had allergic diseases. Lymphopenia is striking, primarily because of a marked deficiency of T cells; T-cell function is decreased to various degrees. B cell function may be near normal. The proportion of circulating NK cells is increased. Prenatal diagnosis or diagnosis at birth is possible. Bone marrow transplantation is the only successful form of therapy.

**CARTILAGE HAIR HYPOPLASIA**

Cartilage hair hypoplasia (CHH) is an unusual form of short-limbed dwarfism with frequent and severe infections. It occurs predominantly among the Amish, but non-Amish patients have been described.

**Genetics and Pathogenesis**

CHH is an autosomal recessive condition. Numerous mutations that cosegregate with the CHH phenotype have been identified in the untranslated RNase MRP (RMRP) gene, which has been mapped to chromosome 9p21-p13 in Amish and Finnish families (see Table 126-1). The RMRP endoribonuclease consists of an RNA molecule bound to several proteins and has at least 2 functions: cleavage of RNA in mitochondrial DNA synthesis and nucleolar cleaving of pre-rRNA. Mutations in RMRP cause CHH by disrupting a function of RMRP RNA that affects multiple organ systems. In vitro studies show decreased numbers of T cells and defective T-cell proliferation because of an intrinsic defect related to the G1 phase, resulting in a longer cell cycle for individual cells. NK cells are increased in number and function.

**Clinical Manifestations**

Clinical features include short, pudgy hands; redundant skin; hyperextensible joints of hands and feet but an inability to extend the elbows completely; and fine, sparse, light hair and eyebrows. Severe and often fatal varicella infections, progressive vaccinia, and vaccine-associated poliomyelitis have been observed. Associated conditions include deficient erythropoiesis, Hirschsprung disease, and an increased risk of malignancies. The bones radiographically show scaphoiding and sclerotic or cystic changes in the metaphyses and flaring of the costochon-
mitogens but no response to antigens. The thymus and other lymphoid organs are severely hypoplastic, and the lack of class II molecules results in abnormal thymic selection with circulating CD4 T cells that have altered CDR3 profiles.

**IMMUNODEFICIENCY WITH THROMBOCYTOPENIA AND ECZEMA (WISKOTT-ALDRICH SYNDROME)**

Wiskott-Aldrich syndrome, an X-linked recessive syndrome, is characterized by atopic dermatitis, thrombocytopenic purpura with normal-appearing megakaryocytes but small defective platelets, and undue susceptibility to infection.

**Genetics and Pathogenesis**

The abnormal gene, on the proximal arm of the X chromosome at Xp11.22-11.23 near the centromere, encodes a 501 amino acid proline-rich cytoplasmic protein restricted in its expression to hematopoietic cell lineages. The Wiskott-Aldrich syndrome protein (WASP) binds CDC42H2 and rac, members of the Rho family of guanosine triphosphatases. Wiskott-Aldrich syndrome protein appears to control the assembly of actin filaments required for microvesicle formation downstream of protein kinase C and tyrosine kinase signaling. Carriers can be detected by demonstration of the deleterious mutation.

**Clinical Manifestations**

Patients often have prolonged bleeding from the circumcision site or bloody diarrhea during infancy. The thrombocytopenia is not initially due to antiplatelet antibodies. Atopic dermatitis and recurrent infections usually develop during the 1st yr of life. Streptococcus pneumoniae and other bacteria having polysaccharide capsules cause otitis media, pneumonia, meningitis, and sepsis. Later, infections with agents such as *P. jiroveci* and the herpesviruses become more frequent. Survival beyond the teens is rare; infections, bleeding, and EBV-associated malignancies are major causes of death.

Patients with this defect uniformly have an impaired humoral immune response to polysaccharide antigens, as evidenced by absent or markedly diminished isohemagglutinins, and poor or absent antibody responses after immunization with polysaccharide vaccines. IgG1 subclass concentrations, surprisingly, are normal. Anamnestic responses to protein antigens are poor or absent. There is an accelerated rate of synthesis as well as hypercatabolism of albumin, IgG, IgA, and IgM, resulting in highly variable concentrations of different immunoglobulins, even within the same patient. The predominant immunoglobulin pattern is a low serum level of IgM, elevated IgA and IgE, and a normal or slightly low IgG concentration. Because of their profound antibody deficiencies, these patients should be given monthly infusions of intravenous immunoglobulin (IVIG) regardless of their serum levels of the different immunoglobulin isotypes. Percentages of T cells are moderately reduced, and lymphocyte responses to mitogens are variably depressed.

**Treatment**

Good supportive care includes appropriate nutrition, routine IVIG, use of killed vaccines, aggressive management of eczema and associated cutaneous infections, platelet transfusion for serious bleeding episodes, splenectomy if a transplant is not going to be done, and high-dose IVIG with systemic steroids for autoimmune complications. Bone marrow or cord blood transplantation is the treatment of choice and is usually curative.

**ATAXIA-TELANGEICTASIA**

Ataxia-telangiectasia is a complex syndrome with immunologic, neurologic, endocrinologic, hepatic, and cutaneous abnormalities.

**Genetics and Pathogenesis**

The mutated gene responsible for this defect, ataxia-telangiectasia mutation (ATM), was mapped to the long arm of chromosome 11 (11q22-23) and has been cloned. The gene product is a DNA-dependent protein kinase localized predominantly to the nucleus and involved in mitogenic signal transduction, meiotic recombination, and cell-cycle control. Cells from patients, as well as from heterozygous carriers, have increased sensitivity to ionizing radiation, defective DNA repair, and frequent chromosomal abnormalities.

In vitro tests of lymphocyte function have generally shown moderately depressed proliferative responses to T- and B-cell mitogens. Percentages of CD3 and CD4 T cells are moderately reduced, with normal or increased percentages of CD8 and elevated numbers of Th1/Th2 T cells. The thymus is very hypoplastic, exhibits poor organization, and lacks Hassall corpuscles.

**The most prominent clinical features are progressive cerebellar ataxia, oculo-cutaneous telangiectasia, chronic sinopulmonary disease, a high incidence of malignancy, and variable humoral and cellular immunodeficiency. Ataxia typically becomes evident soon after these children begin to walk and progresses until they are confined to a wheelchair, usually by the age of 10-12 yr. The telangiectasias begin to develop at 3-6 yr of age. The most frequent humoral immunologic abnormality is the selective absence of IgA, which occurs in 50-80% of these patients. Hypercatabolism of IgA also occurs. IgE concentrations are usually low, and the IgM may be of the low-molecular-weight variety. IgG2, or total IgG levels may be decreased, and specific antibody titers may be decreased or normal. Recurrent sinopulmonary infections occur in approximately 80% of these patients. Although common viral infections have not usually resulted in untoward sequelae, fatal varicella has occurred. The malignancies associated with ataxia-telangiectasia are usually of the lymphoreticular type, but adenocarcinomas also occur. Unaffected relatives have an increased incidence of malignancy.

**Defects of Innate Immunity**

A number of defects in non–antigen-specific immunity (innate immunity) affect antigen-specific immune responses, as there is interaction between the adaptive and innate immune systems.

**INTERFERON-γ RECEPTORS 1 AND 2, IL-12 RECEPTOR β1, AND IL-12P40 MUTATIONS**

Disseminated BCG and other severe nontuberculosis mycobacterial infections (sepsis, osteomyelitis) occur in patients with severe T-cell defects; however, no specific host defect is identified in approximately half of such cases. The first report was a 2.5 mo old Tunisian girl with fatal idiopathic disseminated BCG infection; 4 children from Malta had disseminated atypical mycobacterial infections in the absence of a recognized immunodeficiency. There was consanguinity in all, and all had a functional defect in the upregulation of tumor necrosis factor (TNF) α production by their blood macrophages in response to stimulation with interferon-γ (IFN-γ). All also had a mutation in the gene on chromosome 6q22-q23 that encodes the IFN-γ receptor 1 (IFN-γR1). IFN-γR1 deficiency may be inherited as a complete autosomal recessive (early onset ≈3 yr of age, more episodes, more severe disease, and higher mortality) or partial dominant (onset ≈10 yr of age) disease. Patients with mutations in the IFN-γR2 have also been identified. Related defects were found in other patients who had disseminated mycobacterial infections, who have mutations in either the gene encoding the β1 chain of the IL-12 receptor (IL-12Rβ1) or in the gene encoding IL-12p40. IL-12 is a powerful inducer of IFN-γ production by T and NK cells, and the mutated receptor chain gene resulted in unresponsiveness of the cells of these patients to IL-12 and inadequate IFN-γ production. The children deficient in IFN-γR1, IFN-γR2, IL-12Rβ1, or IL-12p40 appeared not to be susceptible to infection with many agents other than mycobacteria (occasionally *Salmonella, Listeria, Histoplasma*). Th1 responses appeared to be normal in these patients, and the susceptibility to mycobacterial infections thus apparently results from an intrinsic impairment of the IFN-γ pathway response to these particular intracellular pathogens, showing that IFN-γ is obligatory for efficient macrophage antimycobacterial activity.
GERMLINE STAT-1 MUTATION

Interferons induce the formation of 2 transcriptional activators: gamma-activating factor (GAF) and interferon-stimulated gamma factor 3 (ISGF3). A natural heterozygous dominant germline STAT-1 mutation associated with susceptibility to mycobacterial but not viral disease was found in 2 unrelated patients with unexplained mycobacterial disease. This mutation caused a loss of GAF and ISGF3 activation but was dominant for 1 cellular phenotype and recessive for the other. The mutation impaired the nuclear accumulation of GAF, but not of ISGF3, in cells stimulated by interferons, implying that the antymycobacterial but not the antiviral effects of human interferons are mediated by GAF. Two patients were identified with homozygous STAT-1 mutations; they developed both post-BCG vaccination disseminated disease and lethal viral infections. The mutations in these patients caused a complete lack of STAT-1 and resulted in a lack of formation of both GAF and ISGF3.

IL-1R-ASSOCIATED KINASE 4 DEFICIENCY AND MYELOID DIFFERENTIATION FACTOR 88

Members of IL-1R and the Toll-like receptor superfamilies share an intracytoplasmic Toll-IL-1 receptor (TIR) domain, which mediates recruitment of the IL-1R-associated kinase (IRAK) complex via TIR-containing adapter molecules. Three unrelated, otherwise healthy children with recurrent pyogenic infections caused by pneumococci and staphylococci had normal immunocompetence by standard immune studies. They had normal titers of antipneumococcal antibodies. Their blood and fibroblast cells did not activate nuclear factor κB, and mitogen-activated protein kinase and failed to induce downstream cytokines in response to any of the known ligands of TIR-bearing receptors. All were found to have an inherited deficiency of IRAK-4. The TIR-IRAK signaling pathway appears to be crucial for protective immunity against specific bacteria but is redundant against most other microorganisms. There are now more than 50 documented cases of IRAK4 deficiency, and a commonality among cases is susceptibility to pyogenic bacterial infection with pneumococcus and Pseudomonas. The pneumococcal infections have the potential to be invasive (even as a presenting feature) and lead to poor clinical outcomes. Severe viral and fungal infections are atypical. The myeloid differentiation factor 88 (MYD88) is an effective phenocopy of IRAK4 deficiency. While discovered later than IRAK4 deficiency, myeloid differentiation factor 88 is an upstream adaptor for IRAK4 and links it to Toll-like receptors, which results in a very similar immunologic defect and clinical syndrome.

NATURAL KILLER CELL DEFICIENCY

NK cells are the major lymphocytes of the innate immune system. NK cells recognize virally infected and malignant cells and mediate their elimination. Individuals with absence or functional deficiencies of NK cells are rare, and they typically have susceptibility to the herpesviruses (including varicella-zoster virus, herpes simplex virus, cytomegalovirus, and EBV) as well as papillomaviruses. A number of gene defects are associated with these isolated abnormalities in NK cells. Autosomal recessive CD16 gene mutations were described in 3 separate families and they altered the first immunoglobulin-like domain of this important NK cell activation receptor. Patients with these mutations have NK cells that are functionally impaired and have clinical susceptibility to herpesviruses. Autosomal dominant deficiency of NK cells occurs in individuals with mutations in the GATA2 transcription factor. These patients also have low numbers of monocytes. They have extreme susceptibility to human papilloma virus as well as mycobacteria—the latter presumably from the monocytic defect. Autosomal recessive mutations in the MCM4 gene have been identified in a cohort of congenitally normal Irish women who had growth failure and susceptibility to herpesviruses. These individuals possessed the immature CD56dimCD16bright minor subset, but lacked the major mature CD56dim subset of NK cells. The reason why MCM4, which encodes a DNA helicase, would interfere with NK cell development remains unclear. Therapeutically, patients should be maintained on antiviral prophylaxis, and allogeneic stem cell transplantation has been successful in certain cases.

HYPER-IGE SYNDROMES

The hyper-ige syndromes are relatively rare primary immunodeficiency syndromes characterized by recurrent severe staphylococcal abscesses of the skin, lungs, and other sites and markedly elevated levels of serum IgE (Table 126-3). They occur in 2 forms: autosomal dominant and autosomal recessive.

Autosomal Dominant Hyper-IgE Syndrome

This is the most common form in the United States. More than 200 patients with autosomal dominant hyper-IgE syndrome, also known as the Buckley syndrome, have been reported.

Genetics and Pathogenesis

The autosomal dominant hyper-ige syndrome is caused by heterozygous mutations in the gene encoding STAT-3. These mutations result in a dominant negative effect on the expression of STAT-3 by the other nonmutated gene. It is not clear exactly how the STAT-3 mutation causes all parts of the syndrome, but it is thought that IL-17 deficiency may account in part for the susceptibility to Candida infection. IL-17 is a cytokine that acts on monocytes to induce secretion of proinflammatory mediators such as IL-8, TNF, and granulocyte-macrophage colony-stimulating factor.

Clinical Manifestations

The characteristic clinical features of the autosomal dominant form of the hyper-ige syndrome are staphylococcal abscesses, pneumatoceles, osteopenia, and unusual facial features. There is a history from infancy of recurrent staphylococcal abscesses involving the skin, lungs, joints, and other sites. Persistent pneumatoceles develop as a result of recurrent pneumonia. They often have histories of sinusitis and mastoiditis. C. albicans is the second most common pathogen. Allergic respiratory symptoms are usually absent. The pruritic dermatitis that occurs is not typical atopic eczema and does not always persist. The first 2 reported patients were described as having coarse facial features, including a prominent forehead, deep-set wide-spaced eyes, a broad nasal bridge, a wide fleshy nasal tip, mild prognathism, facial asymmetry, and hemihypertrophy. In older children, delay in shedding primary teeth, recurrent fractures, and scoliosis occur.

These patients demonstrate an exceptionally high serum IgE concentration; an elevated serum IgD concentration; usually normal concentrations of IgG, IgA, and IgM; pronounced blood and sputum eosinophilia; abnormally low anamnestic antibody responses; and poor antibody and cell-mediated responses to neoantigens. Traditionally, IgE levels >2000 IU/mL confirm the diagnosis. However, IgE levels may fluctuate and even decrease in adults. In neonates and infants with the pruritic purulant dermatosis, IgE levels will be elevated for age and are usually in the 100s. In vitro studies show normal percentages of blood T, B, and NK lymphocytes, except for a decreased percentage of T cells with the memory (CD45RO) phenotype and an absence or deficiency of Th17 T cells. Most patients have normal T-lymphocyte proliferative responses to mitogens but very low or absent responses to antigens or allogeneic cells from family members. Blood, sputum, and histologic sections of lymph nodes, spleen, and lung cysts show striking eosinophilia. Hassall corpuscles and thymic architecture are normal. Phagocytic cell ingestion, metabolism, killing, and total hemolytic complement activity are normal in all patients, and results of chemotaxis studies have been mostly normal.

Autosomal Recessive Hyper-IgE Syndrome

Genetics and Pathogenesis

With the exception of 1 patient who had a mutation in the gene encoding Tyk2, most reported patients with autosomal recessive hyper-IgE syndrome have had mutations in the gene encoding DOCK8, which is on chromosome 9. DOCK8 is a member of the 11-member DOCK protein family. DOCK8 is likely to function as a guanine exchange factor for the Rho guanosine triphosphatases Cdc42 and Rac1. Guanosine triphosphatase activation induces dynamic filamentous actin rearrangements and lamellipodia formation, leading to cell growth, migration, and adhesion. DOCK8 may be important for the formation of inflammatory mediators.
of the immunologic synapse that leads to T-cell activation, proliferation, and differentiation. Of the 33 patients reported, 25 were from Turkey, 2 each were from Mexico and Iran, and 1 each was from Lebanon, Oman, Italy, and Ireland. Autosomal recessive hyper-IgE syndrome may rarely be due to mutations in phosphoglucomutase 3 (PGM3 deficiency).

### Clinical Manifestations
Unlike those with the autosomal dominant form of this syndrome, a large majority of patients with autosomal recessive hyper-IgE have severe atopic dermatitis, asthma, food allergies, and anaphylaxis. They also have recurrent skin viral infections, including severe herpes simplex, herpes zoster, molluscum contagiosum, and papillomavirus skin infections (see Table 126-3). In addition, patients can have abscesses, mucocutaneous candidiasis, upper respiratory infections, and pneumonia. Neurologic problems, including strokes, meningitis, and aneurysms, are prominent. Malignancies are also more common than in the autosomal dominant form. Patients with the autosomal recessive hyper-IgE syndrome do not have pneumatoceles, a history of fractures, unusual facial features, or delayed shedding of the baby teeth, as seen with the autosomal dominant form of the hyper-IgE syndrome (see Table 126-3).

Most patients with autosomal recessive hyper-IgE have elevated serum IgE levels, low serum IgM levels, and variable IgG antibody responses. They also have eosinophilia and lymphopenia, low T-cell numbers and impaired T-cell function. Their immunologic phenotype is that of a CID.

### Treatment
The most effective therapy for the autosomal dominant hyper-IgE syndrome is long-term administration of therapeutic doses of a penicillinase-resistant antibacterial antibiotic, adding other agents as required for specific infections. IVIG should be administered to antibody-deficient patients, and appropriate thoracic surgery should be provided for superinfected pneumatoceles or those persisting beyond 6 mo. Bone marrow transplantation has been variably successful in this condition. The prognosis in the autosomal recessive form of the hyper-IgE syndrome is much poorer than in the autosomal dominant form, and most patients die early (see Table 126-3). The treatment of choice for the autosomal recessive form is allogeneic bone marrow transplantation.

### 126.4 Treatment of Cellular or Combined Immunodeficiency
Rebecca H. Buckley

Good supportive care, including prevention and treatment of infections, is critical while patients await more definitive therapy (Table 126-4). Having knowledge of the pathogens causing disease with specific immune defects is also useful (see Table 126-4).

Transplantation of MHC-compatible sibling or rigorously T-cell-depleted haploidentical (half-matched) parental hematopoietic stem cells is the treatment of choice for patients with fatal T-cell or combined T- and B-cell defects. The major risk to the recipient from transplantation of bone marrow or peripheral blood stem cells is GVHD from donor T cells. Patients with less severe forms of cellular immunodeficiency, including some forms of CID, Wiskott-Aldrich syndrome, cytokine deficiency, and MHC antigen deficiency, reject even HLA-identical marrow grafts unless chemoablative treatment is given before transplantation. Several patients with these conditions have been treated successfully with hematopoietic stem cell transplantation after conditioning.

More than 90% of patients with primary immunodeficiency transplanted with HLA-identical related marrow will survive with immune reconstitution. T-cell–depleted haploidentical-related marrow transplants in patients with primary immunodeficiency have had their greatest success in patients with SCID, who do not require...
pretransplant conditioning or GVHD prophylaxis. Of patients with SCID, 92% have survived after T-cell–depleted parental marrow is given soon after birth when the infant is healthy without pretransplant chemotherapy or posttransplant GVHD prophylaxis. Currently, bone marrow transplantation remains the most important and effective therapy for SCID. Early in 2000, there was remarkable success with gene therapy in X-SCID. Unfortunately, leukemic-like clonal T cells or lymphomas developed in 5 of 20 children so treated as a result of insertional mutagenesis, which led to a cessation of those trials. By contrast, in ADA-deficient SCID, there has been outstanding success without insertional oncogenesis. More recently, gene therapy has been successful in the Wiskott–Aldrich syndrome but unfortunately with the problem of insertional mutagenesis.

126.5 Immune Dysregulation with Autoimmunity or Lymphoproliferation

Rebecca H. Buckley

AUTOIMMUNE LYMPHOPROLIFERATIVE SYNDROME

Autoimmune lymphoproliferative syndrome (ALPS), also known as Canale-Smith syndrome, is a disorder of abnormal lymphocyte apoptosis leading to polyclonal populations of T cells (double-negative T cells), which express CD3 and α/β antigen receptors but do not have CD4 or CD8 coreceptors (CD3 + T cell receptor α/β CD4–CD8–). These T cells respond poorly to antigens or mitogens and do not produce growth or survival factors (IL-2). The genetic deficit in most patients is a germline or somatic mutation in the Fas gene, which produces a cell-surface receptor of the TNF receptor superfamily (TNFRSF6), which, when stimulated by its ligand, will produce programmed cell death (Table 126-5). Persistent survival of these lymphocytes leads to immune dysregulation and autoimmunity. ALPS is also caused by other genes in the Fas pathway (FASLG and CASP10). In addition, ALPS-like disorders are associated with other mutations; RAS-associated autoimmune lymphoproliferative disorder (RALD), CAPSASE-8 deficiency syndrome (CEDS), Fas-associated protein with death domain deficiency (FADD), and protein kinase C delta deficiency (PRKCD). These disorders have varying degrees of immune deficiency, autoimmunity and lymphoproliferation.

Clinical Manifestations

ALPS is characterized by autoimmunity, chronic persistent or recurrent lymphadenopathy, splenomegaly; hepatomegaly (in 50%), and hypergammaglobulinemia (IgG, IgA). Many patients present in the 1st yr of life, and most are symptomatic by yr 5. Lymphadenopathy can be striking (Fig. 126-2). Splenomegaly may produce hypersplenism with cytopenias. Autoimmunity also produces anemia (Coombs-positive hemolytic anemia) or thrombocytopenia or a mild neutropenia. The lymphoproliferative process (lymphadenopathy, splenomegaly) may regress over time, but autoimmunity does not and is characterized by frequent exacerbations and recurrences. Other autoimmune features include urticaria, uveitis, glomerulonephritis, hepatitis, vasculitis, glomerulonephritis, vasculitis, panniculitis, arthritis, and central nervous system involvement (seizures, headaches, encephalopathy).

Malignancies are also more common in patients with ALPS and include Hodgkin and non-Hodgkin lymphomas and solid-tissue tumors of thyroid, skin, heart, or lung. ALPS is one cause of Evan syndrome (immune thrombocytopenia and immune hemolytic anemia).

Diagnosis

Laboratory abnormalities depend on the lymphoproliferative organ response (hypersplenism) or the degree of autoimmunity (anemia, thrombocytopenia). There may be lymphocytosis or lymphopenia. Table 126-5 lists the criteria for the diagnosis. Flow cytometry helps identify the lymphocyte type (see Fig. 126-2). Functional genetic analysis for the TNFRSF6 gene often reveals a heterozygous mutation.

Treatment

Lymphoproliferative manifestations have been managed with corticosteroids and immunosuppressive agents (Cytoxan [cyclophosphamide], methotrexate, azathioprine); once weaned, the manifestation recurs. Hypersplenism may require splenectomy. Malignancies can be treated with the usual protocols used in patients unaffected by ALPS. Stem cell transplantation is another possible option in treating the autoimmune manifestations of ALPS.

**IMMUNE-DYSREGULATION, POLYENDOCRINOPATHY, ENTEROPATHY, X-LINKED SYNDROME**

This immune dysregulation syndrome is characterized by onset within the 1st few wk or mo of life with watery diarrhea (autoimmune enteropathy), an eczematous rash (erythroderma in neonates), insulin-dependent diabetes mellitus, hyperthyroidism or more often hypothyroidism, severe allergies, and other autoimmune disorders (Coombs-positive hemolytic anemia, thrombocytopenia, neutropenia). Psoriasiform or ichthyosiform rashes and alopecia have also been reported.

Immune-dysregulation, polyendocrinopathy, enteropathy, X-linked (IPEX) syndrome is caused by a mutation in the **FOXP3** gene, which encodes a forkhead-winged helix transcription factor (scurfin) involved in the function and development of CD4<sup>+</sup>CD25<sup>+</sup> regulatory T cells. The absence of regulatory cells may predispose to abnormal activation of effector T cells. Dominant gain of function mutations in **STAT1** and other gene mutations (Table 126-6) produces an IPEX-like syndrome.

**Clinical Manifestations**

Watery diarrhea with intestinal villous atrophy leads to failure to thrive in most patients. Cutaneous lesions (usually eczema) and

**DIAGNOSIS**

Definitive: Required plus 1 primary accessory criterion

Probable: Required plus 1 secondary accessory criterion

Of note, probable and definitive ALPS should be treated the same in the clinic.

*Modified from Teachey DT: New advances in the diagnosis and treatment of autoimmune lymphoproliferative syndrome. Curr Opin Pediatr 24:1–8, 2013, Table 2, p. 4.*

Figure 126-2 Clinical, radiographic, immunologic, and histologic characteristics of the autoimmune lymphoproliferative syndrome. A, Front view of the National Institutes of Health patient. B, Top middle, a CT scan of the neck is shown demonstrating enlarged preauricular, cervical, and occipital lymph nodes. Arrowheads denote the most prominent lymph nodes. The top right panels show the flow-cytometric analysis of peripheral blood T cells from a patient with autoimmune lymphoproliferative syndrome (ALPS), with CD8 expression on the vertical axis and CD4 on the horizontal axis. The lower left quadrant contains CD4<sup>+</sup>CD8<sup>+</sup> (double-negative) T cells, which are usually present at <1% of T cells expressing the αβ T-cell receptor. The bottom panels show CD3, CD4, and CD8 staining on serial sections of a lymph node biopsy specimen from a patient with ALPS and also shows that large numbers of DN<sup>CD3</sup><sup>+</sup>CD4<sup>+</sup>CD8<sup>-</sup> (double-negative) T cells are present in the interfollicular areas of the lymph node. (Adapted from Siegel RM, Fleisher TA: The role of Fas and related death receptors in autoimmune and other disease states, J Allergy Clin Immunol 103:729–738, 1999.)
insulin-dependent diabetes begin in infancy. Lymphadenopathy and splenomegaly are also present. Serious bacterial infections (meningitis, sepsis, pneumonia, osteomyelitis) may be related to neutropenia, malnutrition, or immune dysregulation. Laboratory features reflect the associated autoimmune diseases, dehydration, and malnutrition. In addition, serum IgE levels are elevated with normal levels of IgM, IgG, and IgA. The diagnosis is made clinically and by mutational analysis of the FOXP3 gene.

**Treatment**

Inhibition of T-cell activation by cyclosporine, tacrolimus, or sirolimus with steroids is the treatment of choice, along with the specific care of the endocrinopathy and other manifestations of autoimmunity. Stem cell transplantation is the only possibility for curing IPEX. Overall, the combination of the risks for serious bacterial infection in the untreated condition and the risks of immunosuppression and bone marrow transplantation gives IPEX a poor prognosis. Untreated, most die by 2 yr of age.

Chapter 127
Neutrophils
Thomas D. Coates

THE PHAGOCYTIC INFLAMMATORY RESPONSE
The phagocyte system includes both granulocytes (neutrophils, eosinophils, and basophils) and mononuclear phagocytes (monocytes and tissue macrophages). Neutrophils and mononuclear phagocytes share primary functions, including the defining properties of large particle ingestion and microbial killing. Phagocytes participate primarily in the innate immune response but also help initiate acquired immunity. Mononuclear phagocytes, including tissue macrophages and circulating monocytes, are discussed in Chapter 128.

Neutrophils provide the rapid effector arm of the innate immune system. They circulate in the bloodstream for only about 6 hours (Table 127-1), but upon encountering specific chemotactic signals, they adhere to the vascular endothelium and transmigrate into tissues, where they ingest and kill microbes and release chemotactic signals to recruit more neutrophils and to attract dendritic cells and other initiators of the acquired immune response.

HEMATOPOIESIS
The hematopoietic progenitor system can be envisioned as a continuum of functional compartments with the most primitive compartment composed of very rare pluripotent stem cells, which have high self-renewal capacity and give rise to more mature stem cells, including cells that are committed to either lymphoid or myeloid development (Fig. 127-1). Common lymphoid progenitor cells give rise to

Figure 127-1 Major cytokine sources and actions and transcription factor requirements. Cells of the bone marrow microenvironment such as macrophages, endothelial cells, and reticular fibroblastoid cells, produce macrophage colony-stimulating factor (M-CSF), granulocyte-macrophage colony-stimulating factor (GM-CSF), granulocyte colony-stimulating factor (G-CSF), interleukin (IL)-6, and probably stem cell factor (SCF) after induction with endotoxin (macrophage) or IL-1/tumor necrosis factor (TNF) (endothelial cells and fibroblasts). T-cells produce IL-3, GM-CSF, and IL-5 in response to antigenic and IL-1 stimulation. These cytokines have overlapping actions during hematopoietic differentiation, as indicated, and for all lineages optimal development requires a combination of early- and late-acting factors. Transcription factors important for survival or self-renewal of stem cells are shown at the top (light green panel) and stages of hematopoiesis blocked after the depletion of indicated transcription factors for multipotent and committed progenitors are shown in light green boxes throughout. CFU-E, erythroid colony-forming unit; CFU-Eo, eosinophil colony-forming unit; CFU-G, granulocyte colony-forming unit; CFU-M, macrophage colony-forming unit; MSC, myeloid stem cells; NK, natural killer; PSC, pluripotent stem cells. (From Nathan DG, Orkin SH, Ginsburg D, et al, editors: Nathan and Oski’s hematology of infancy and childhood, ed 7, Philadelphia, 2009, WB Saunders.)

T- and B-cell precursors and their mature progeny (see Chapter 123). Common myeloid progenitor cells eventually give rise to committed single-lineage progenitors of the recognizable precursors through a random process of lineage restriction in a stepwise process (see Chapter 446). The capacity of lineage-specific committed progenitors to proliferate and differentiate in response to demand provides the hematopoietic system with a remarkable range of response to changing requirements for mature blood cell production.

The proliferation, differentiation, and survival of immature hematopoietic progenitor cells are governed by hematopoietic growth factors, a family of glycoproteins (see Chapter 446). Besides regulating proliferation and differentiation of progenitors, these factors influence the survival and function of mature blood cells. During granulopoiesis and monopoiesis, multiple cytokines regulate the cells at each stage of differentiation from pluripotent stem cells to non-dividing terminally differentiated cells (monocytes, neutrophils, eosinophils, and basophils). As cells mature, they lose receptors for most cytokines, especially those that influence early cell development; however, they retain receptors for cytokines that affect their mobilization and function, such as granulocyte colony-stimulating factor and macrophage colony-stimulating factor. Mature phagocytes also express receptors for chemokines, which help direct the cells to sites of inflammation. Chemokine receptors such as CXCR4 and its ligand SDF-1 play a key role in retention of developing myeloid cells within bone marrow.

NEUTROPHIL MATURATION AND KINETICS

The process of intramedullary granulocyte maturation involves changes in nuclear configuration and accumulation of specific intracytoplasmic granules. The bone marrow microenvironment supports the normal steady-state renewal of peripheral blood neutrophils through the generation of growth and differentiation factors by stromal cells. Growth factors such as granulocyte colony-stimulating factor and granulocyte-macrophage colony-stimulating factor not only stimulate cell division, but also induce the expression of transcription factors that regulate the biosynthesis of functional components of the neutrophil, such as granule proteins. The transcription factor PU.1 is essential for myelopoiesis, both as a positive regulatory element and as a suppressor of GATA-1, a transcription factor that directs nonmyeloid differentiation. Other transcription factors, such as Runx1 (AML1), c-myc, CDP, C/EBPα, C/EBPδ, and MEF, are expressed in the myeloblast and pro-mycocyte, and some of these are required for azurophil granule protein expression. As cells enter the myelocyte stage, RUNX1 and
myb are downregulated, whereas PU.1 and C/EBPε expression rises to initiate terminal differentiation.

Granulocytes survive for only 6-12 hr in the circulation, and therefore daily production of $2 \times 10^4$ granulocytes/µL of blood is required to maintain a level of circulating granulocytes of $5 \times 10^7$/µL (see Table 127-1). The relatively small peripheral blood pool includes the rapidly interchanging circulating and marginating pools; the latter provides entrance into the tissue phase, where neutrophils may survive for hours or days. The circulating pool is fed and buffered by a much larger marrow population of mature neutrophils and myeloid precursors, representing the marrow reserve and proliferating pools, respectively. Proliferation of myeloid cells, encompassing approximately 5 mitotic divisions, takes place only during the 1st 3 stages of neutrophil development, in myeloblasts, promyelocytes, and myelocytes. After the myelocyte stage, the cells terminally differentiate into nondividing, maturing metamyelocytes, bands, and neutrophils.

Neutrophil maturation is associated with nuclear condensation and lobulation and with the sequential production of characteristic granule populations. A myeloblast is a relatively undifferentiated cell with a large oval nucleus, a sizeable nucleolus, and a deficiency of granules. Promyelocytes acquire peroxidase-positive azurophilic (primary) granules, and then myelocytes and metamyelocytes acquire specific (secondary) granules; tertiary granules and secretory vesicles develop in the final stage of neutrophil maturation.

**NEUTROPHIL FUNCTION**

Neutrophil responses are initiated as circulating neutrophils flowing through the postcapillary venules detect low levels of chemokines and other chemotactic substances released from a site of infection. The sequence of events as the neutrophil moves from circulating in the blood to the encounter and destruction of bacteria is carefully orchestrated by a series of biochemical events, defects of which are associated with genetic disorders of neutrophil function (Fig. 127-2). In fact, these disorders of neutrophil function lead to our understanding of the cell biology of phagocyte function. A subset of circulating neutrophils loosely adheres to the endothelium through low-affinity receptors called selectins and rolls along the endothelium forming the marginated pool. Soluble effectors of inflammation trigger subtle changes in surface adhesion molecules on endothelial cells at the site of infection. The rolling of neutrophils allows more intense exposure of neutrophils to activating factors such as tumor necrosis factor or interleukin-1 (Fig. 127-2). Exposure of neutrophils to these same activating factors induces...
qualitative and quantitative changes in the family of β2-integrin adhesion receptors (the CD11/CD18 group of surface molecules), leading to tight adhesion between neutrophils and endothelial cells at the site of inflammation and ultimately to transmigration of the neutrophil into the tissue.

Once through the endothelium, the neutrophil senses the gradient of chemokines or other chemoattractants and migrates to sites of infection. Neutrophil migration is a complex process involving rounds of receptor engagement, signal transduction, and remodeling of the actin-microfilaments composing in part the cytoskeleton. Actin polymerization–depolymerization occurs in approximately 8 sec cycles and drives cyclic extension and retraction of the actin-rich lamella at the front of the neutrophil. Receptors at the leading edge of the lamella detect the gradient of attractant and follow microorganisms, ingest and destroy them. When the neutrophil reaches the site of infection, it recognizes pathogens by means of Fc immunoglobulin and complement receptors, Toll-like receptors, fibronectin receptors, and other adhesion molecules.

The neutrophils ingest microbes that are coated by opsonins, serum proteins such as immunoglobulin and complement component C3. The pathogens are engulfed into a closed vacuole, the phagosome (Fig. 127-3) where 2 cellular responses essential for optimal microbicidal activity occur concomitantly: degranulation and activation of nicotinamide-adenine dinucleotide phosphate (NADPH)–dependent oxidase. Fusion of neutrophil granule membranes with the phagosome membrane delivers potent antimicrobial proteins and small peptides into the phagosome.

Assembly and activation of NADPH oxidase at the phagosome membrane as well (see Fig. 127-3) generating large amounts of superoxide (O2•−) from molecular oxygen that, in turn, decomposes to produce hydrogen peroxide (H2O2) and singlet oxygen. Myeloperoxidase, a major azurophil granule component, catalyzes the reaction of H2O2 with ubiquitously present chloride ions to create hypochlorous acid (HOCl) in the phagosome. Hypochlorous acid is essentially Clorox bleach. H2O2 and HOCl are potent microbicidal agents that break down and clear pathogens from sites of infection.

In addition, neutrophils secrete a wide variety of cytokines and chemokines that recruit more neutrophils to fight the infection, attract monocytes and macrophages that possess both microbicidal and scavenger functions, and promote antigen presentation to help initiate the adaptive immune response. Also, the reactive oxidants can inactivate chemotactic factors and may serve to terminate the process of neutrophil influx, thereby attenuating the inflammatory process. Finally, the release of reactive oxygen species, granule proteins, and cytokines can also damage local tissues, leading to the classic signs of inflammation or to more permanent impairment of tissue integrity and function.

Bibliography is available at Expert Consult.
Bibliography
Mononuclear phagocytes (monocytes, macrophages) are distributed across all body tissues and play a central role in maintaining homeostasis. They are essential for innate host defense against infection, tissue repair and remodeling, and the antigen-specific adaptive immune response. No human has been identified as having congenital absence of this cell line, probably because macrophages are required to remove primitive tissues during fetal development as new tissues develop to replace them. Monocytes and tissue macrophages in their several forms (Table 128-1) have variable morphology and surface markers and different transcriptional profiles but common functions, particularly phagocytosis. Dendritic cells (DCs) are specialized derivatives of this system that develop from myeloid–lymphoid cell precursors.

**DEVELOPMENT**

Monocytes develop more rapidly during bone marrow hematopoiesis and remain longer in the circulation than do neutrophils (see Table 127-1). The first recognizable monocyte precursor is the monoblast, followed by the promonocyte with cytoplasmic granules and an indented nucleus, and, finally, the fully developed monocyte with cytoplasm filled with granules containing hydrolytic enzymes. The transition from monoblast to mature circulating monocyte requires about 6 days.

Two major subsets of human blood monocytes can be identified on the basis of surface antigens: CD14++ CD16−, originally termed
**Part XIV**

**Upregulated Functions in Macrophages**

It seems likely that so-called classically and alternatively activated macrophages are examples of a continuum of physiologic functions expressed by these long-lived cells in response to the specific task at hand.

Classical macrophage activation is accomplished during infection with intracellular pathogens (e.g., mycobacteria, *Listeria*), through cross-talk between Th1 lymphocytes and antigen-presenting macrophages mediated by the engagement of a series of ligands and receptors on the 2 cell types, including CD40 on macrophages and CD40 ligand on Th cells, and through secretion of cytokines. Macrophages encountering microorganisms release IL-12, which stimulates T cells to release IFN-γ. These interactions constitute the basis of cell-mediated immunity. IFN-γ is an especially important macrophage-activating cytokine; it is currently used as a therapeutic agent.

**Functional Activities**

Numerous functions are upregulated when the macrophage is activated in response to infection (see Table 128-2). Obviously important are the ingestion and killing of intracellular pathogens such as mycobacteria, *Listeria, Leishmania, Toxoplasma,* and some fungi; however, splenic and hepatic macrophages also clear extracellular pathogens such as pneumococci from the bloodstream. Killing of the ingested organisms depends heavily on products of the respiratory burst (e.g., hydrogen peroxide and on nitric oxide, and release of these metabolites is enhanced in activated macrophages.

The activity of mononuclear phagocytes against cancers in humans is less-well understood. This activity may involve more than the phagocytic process. Macrophages may kill tumor cells by means of secreted products, including lysozymes, nitric oxide, oxygen metabolites, cytolytic proteinases, and TNF-α. Proteolytic enzymes and cytoidal factors present on the surface membrane of monocytes may have a role in tumor rejection. In contrast, tumor-associated macrophages also appear to stimulate growth of certain tumors through secretion of growth and angiogenic factors.

The capacity to undergo diapedesis across the endothelial wall of blood vessels and to migrate to sites of microbial invasion is essential to monocyte function. Chemotactic factors for monocytes include complement products and chemokines derived from neutrophils, lymphocytes, and other cell types. Phagocytosis of the invading organisms can then occur, influenced by the presence of opsonins for the invader (antibody, complement, mannose-binding and surfactant proteins), the inherent surface properties of the microorganism, and the state of activation of the macrophage.

Monocytes migrating to intestinal mucosa are modified by stromal factors so that they lose innate receptors for microbial products such as bacterial cell wall protein or endotoxin through Toll-like receptors.

as endotoxin, and they do not effectively produce proinflammatory cytokines. They retain, however, the capacity to ingest and kill microbes. They have been modified during evolution to allow the absence of inflammation typical of normal intestinal mucosa in spite of its constant exposure to huge numbers of microbes and their inflammatory by-products. Macrophages play an essential role in the disposal of damaged and dying cells, helping resolve the inflammatory response and heal wounds. Brain microglia demonstrate these functions particularly well. In conditions such as stroke, neurodegenerative disease, and tumor invasion, these cells can become activated, surround damaged and dead cells, and clear cellular debris. Macrophages lining the sinuses of the spleen are especially important in ingesting aged or autoantibody-coated erythrocytes or platelets; splenectomy is used to manage autoimmune cytopenias. Macrophages in inflammatory sites can recognize changes in phosphatidylserine on the membrane of neutrophils undergoing apoptosis, and these can be removed before they become necrotic and spill their toxic contents into the tissue. Macrophages also remove the extracellular traps exuded by inflammatory neutrophils, thus reducing the risk of autoimmunity. Macrophages can be identified early in fetal development, where they function to remove debris as one maturing embryonic tissue replaces another. They are also important in removing immune complexes, protein fragments, and inorganic particles such as elements of cigarette smoke that enter the alveoli.

Macrophages are integrally involved in the induction and expression of adaptive immune responses, including antibody formation and cell-mediated immunity. This involvement depends on their capacity to break down foreign material in phagocytic and pinocytic vesicles and then present individual antigens on their surface as peptides or poly saccharides bound to class II major histocompatibility complex (MHC) molecules. B lymphocytes and, most effectively, DCs can also present antigens to T cells for the specific immune response. Expression of MHC class II molecules is increased in activated macrophages, and antigen presentation is more effective. The heightened capacity of activated macrophages to synthesize and release various hydrolytic enzymes and microbialicidal materials (see Table 128-2) probably plays a part in their increased killing capacity, although not every macrophage product is secreted in increased amounts when the cell is activated. The macrophage is an extraordinarily active secretory cell. It has been shown to secrete more than 100 distinct substances, including cytokines, growth factors, and steroid hormones, placing it in a class with the hepatocyte. Because of the profound effect of some of these secretory products on other cells and the large number and widespread distribution of macrophages, this network of cells can be viewed as an important endocrine organ. IL-1 illustrates this point well. Microbes and microbial products, burns, ischemia–reperfusion, and other causes of inflammation or tissue damage stimulate the release of IL-1, mainly by monocytes, macrophages, and epithelial cells. In turn, IL-1 elicits fever, sleep, and release of IL-6, which induces production of acute-phase proteins.

As traumatic damage and infection subside, the macrophage population shifts toward playing an essential role in tissue repair and healing through removal of apoptotic cells and secretion of IL-10, transforming growth factor-β, lipoxins, and omega-3 fatty acid–derived resolvins, protectins, and maresins (macrophage mediators in resolving inflammation).

**DENDRITIC CELLS**

DCs are derived from both myeloid and lymphoid bone marrow progenitors. They are specialized to capture, process, and present antigens to T cells to generate adaptive immunity or tolerance to self-antigens. Human monocytes can be induced to differentiate into DCs in some circumstances, particularly inflammation. DCs express retractable dendritic (branched) extensions and potent endocytic capacity but are a heterogeneous population from the standpoint of location, surface markers, level of antigen-presenting activity, and function. There are 2 major functional types of DCs, conventional DCs, which include Langherhans cells in the epithelial surfaces of skin and mucosa, and dermal or interstitial DCs in subepithelial skin and interstitia of solid organs; and plasmacytoid DCs, sentinels for viral infection and principal source of antiviral IFN-α and IFN-β.

DCs migrating from the bloodstream enter skin, epithelial surfaces, and lymphoid organs where, as immature cells, they internalize self- and foreign-antigens. Microbial products, cytokines, or molecules exposed in damaged tissue (“danger signals” or “alarmins”) induce DC maturation, with upregulation of cytokine receptors and MHC class II and costimulatory molecules. Stimulated DCs in the periphery migrate to lymphoid organs where they continue to mature. They function there as the most potent cells that present antigens to T lymphocytes and induce their proliferation, activities that are central to the antigen-specific adaptive immune response. Macrophage IL-10 acts to suppress DC maturation during resolution of inflammation.

DCs from cancer patients have been used in an attempt to control their cancer. The patient’s DCs are amplified and matured from blood monocytes or marrow progenitor cells by cytokines, exposed to antigens from the patient’s tumor, then injected into the patient as a “vaccine” against the cancer.

**ABNORMALITIES OF MONOCYTE-MACROPHAGE OR DENDRITIC CELL FUNCTION**

Mononuclear phagocytes, as well as neutrophils, from patients with chronic granulomatous disease exhibit a profound defect of phagocytic killing (see Chapter 130). The inability of affected macrophages to kill ingested organisms leads to abscess formation and characteristic granulomas at sites of macrophage accumulation beneath the skin and in the liver, lungs, spleen, and lymph nodes. IFN-γ is currently used for preventing infection in patients with chronic granulomatous disease and for treating the decreased bone resorption of congenital osteopetrosis, which is caused by decreased function of osteoclasts. Genetic deficiency of the CD11/CD18 complex of membrane adherence glycoproteins (leukocyte adhesion defect-1), which includes a receptor for opsonic complement component 3, results in impaired phagocytosis by monocytes (see Chapter 130).

The monocyte–macrophage system is prominently involved in lipid storage diseases called sphingolipidoses (see Chapter 86.3). In these conditions, the expression in macrophages of a systemic enzymatic defect permits the accumulation of cell debris that is normally cleared. Resistance to infection can be impaired, at least partly because of impairment in macrophage function. Gaucher disease is the prototype for these disorders. In this condition, the enzyme glucocerebrosidase functions abnormally, thus allowing accumulation of glucocerebroside from cell membranes in Gaucher cells throughout the body. In all locations, the Gaucher cell is an altered macrophage. These patients can be treated with infusions of the normal enzyme modulated to expose mannoside residues, which bind to mannose receptors on macrophages.

The cytokine IL-12 is a powerful inducer of IFN-γ production by T cells and natural killer cells. Individuals with inherited deficiency in macrophage receptors for IFN-γ or lymphocyte receptors for IL-12, or in IL-12 itself, suffer a severe, profound, and selective susceptibility to infection by nonnontuberculous mycobacteria such as Mycobacterium avium complex or bacillus Calmette-Guérin (see Chapter 126). About half of these patients have had disseminated Salmonella infection. These abnormalities are now grouped as defects in the IFN-γ–IL-12 axis.

Monocyte–macrophage function has been shown to be partially abnormal in various clinical conditions. Cultured mononuclear phagocytes of newborns are more readily infected than adult cells by HIV-1 and measles virus. Macrophages from newborns release less granulocyte colony-stimulating factor and IL-6 in culture, and this deficiency is accentuated in cells from preterm infants. This finding supports the observations that levels of granulocyte colony-stimulating factor are significantly decreased in blood from newborns, and that the marrow granulocyte storage pool is diminished in infants, particularly preterm infants. Mononuclear cells from newborns produce less IFN-γ and IL-12 than do adult cells, and macrophages cultured from cord blood are not activated normally by IFN-γ. This combination of deficiencies
would be expected to blunt the newborn’s response to infection by viruses, fungi, and certain bacteria such as *Listeria*.

There are 2 disorders in which macrophage activation is pathologically excessive. **Familial and acquired hemophagocytic lymphohistiocytosis** is characterized by uncontrolled activation of T cells and macrophages, with resultant fever, hepatosplenomegaly, lymphadenopathy, pancytopenia, marked elevation of serum proinflammatory cytokines, and macrophage hemophagocytosis (see Chapter 507). Up to 5% of children with systemic onset juvenile rheumatoid arthritis develop an acute severe complication termed **macrophage activation syndrome**, with persistent fever (rather than typical febrile spikes), hepatosplenomegaly, pancytopenia, macrophage hemophagocytosis, and coagulopathy, which can progress to disseminated intravascular coagulation and death if not recognized (see Chapter 155).

Two genetic autoinflammatory diseases result from dysregulation of the mononuclear phagocyte–produced proinflammatory cytokine IL-1. In **neonatal onset multisystem inflammatory disorder** monocytes overproduce IL-1. In **deficiency of the IL-1-receptor antagonist**, normal activity levels of IL-1 go unopposed. In both conditions patients present in the 1st few days or weeks of life with pustular or urticarial rash, bony overgrowth, sterile osteomyelitis, elevated sedimentation rate, and other evidence of systemic inflammation. The recombinant IL-1-receptor antagonist anakinra is effective treatment for both these disorders.

The term **histiocyte** was originally used to describe cells thought to be macrophages in fixed tissue preparations. Histiocytosis X represents a malignancy-like overgrowth of Langerhans-type DCs (see Chapter 507). Thus, the term **Langerhans cell histiocytosis** better describes this disorder, because histiocyte is a histologic term and not cell specific.

Bibliography

Eosinophils are distinguished from other leukocytes by their morphology, constituent products, and association with specific diseases. Eosinophils are nondividing fully differentiated cells with a diameter of ≈8 µm and a bilobed nucleus. They differentiate from stem cell precursors in the bone marrow under the control of T-cell–derived interleukin (IL)-3, granulocyte-macrophage colony-stimulating factor, and, especially, IL-5. Their characteristic membrane-bound specific granules stain reddish brown with eosin and consist of a crystalline core made up of major basic protein (MBP) surrounded by a matrix containing the eosinophil cationic protein, eosinophil peroxidase, and eosinophil-derived neurotoxin. These basic proteins are cytotoxic for the larval stages of helminthic parasites and are also thought to contribute to much of the inflammation associated with chronic allergic diseases such as asthma (see Chapter 144).

Both eosinophil MBP and eosinophil cationic protein are also present in large quantities in the airways of patients who have died of diseases such as asthma (see Chapter 144). Eosinophil granule contents also contribute to Loeffler endocarditis associated with hypereosinophilic syndrome. MBP has the potential to activate other proinflammatory cells, including mast cells, basophils, neutrophils, and platelets. Eosinophils have the capacity to generate large amounts of the lipid mediators platelet-activating factor and leukotriene C4, both of which can cause vasoconstriction, smooth muscle contraction, and mucus hypersecretion. Eosinophils are a source of a number of proinflammatory cytokines, including IL-1, IL-3, IL-4, IL-5, IL-9, IL-13, and granulocyte-macrophage colony-stimulating factor; they can also function as antigen-presenting cells. Thus, eosinophils have considerable potential to initiate and sustain inflammatory response of the innate and acquired immune systems.

Eosinophil migration from the vasculature into the extracellular tissue is mediated by the binding of leukocyte adhesion receptors to their ligands or counterstructures on the postcapillary endothelium. Similar to neutrophils (see Fig. 127-2), transmigration begins as the eosinophil selectin receptor binds to the endothelial carbohydrate ligand in loose association, which promotes eosinophils rolling along the endothelial surface until they encounter a priming stimulus such as a chemotactic mediator. Eosinophils then establish a high-affinity bond between integrin receptors and their corresponding immunoglobulin-like ligand. Unlike neutrophils, which become flattened before transmigrating between the tight junctions of the endothelial cells, eosinophils can use unique integrins, known as VLA-4, to bind to vascular cell adhesion molecule-1, which enhances eosinophil adhesion and transmigration through endothelium. Eosinophils are recruited to tissues in inflammatory states by the chemokine eotaxin. These unique pathways account for selective accumulation of eosinophils in allergic and inflammatory disorders. Eosinophils normally dwell primarily in tissues, especially tissues with an epithelial interface with the environment, including the respiratory, gastrointestinal, and lower genitourinary tracts. The life span of eosinophils may extend for weeks within tissues.

IL-5 selectively enhances eosinophil production, adhesion to endothelial cells, and function. Considerable evidence shows that IL-5 has a pivotal role in promoting eosinophil accumulation. It is the predominant cytokine in allergen-induced pulmonary late-phase reaction, and antibodies against IL-5 block eosinophil infiltration into the lungs in animal models associated with airway hyperresponsiveness following allergen challenge. Eosinophils also bear unique receptors for several chemokines, including RANTES (regulated upon activation, normal T-cell expressed and secreted), eotaxin, and monocyte chemotactic proteins 3 and 4. These chemokines appear to be key mediators in the induction of tissue eosinophilia.

DISEASES ASSOCIATED WITH EOSINOPHILIA
The absolute eosinophil count (AEC) is used to quantify eosinophilia. Calculated as the white blood cell count/µL × percent of eosinophils, it is usually <450 cells/µL and varies diurnally, with eosinophil numbers higher in the early morning and diminishing as endogenous glucocorticoid levels rise. Many diseases with allergic, infectious, hematologic, autoimmune, or idiopathic origins are associated with moderate (AEC 1,500–5,000 cells/µL) or severe (AEC >5,000 cells/µL) eosinophilia in peripheral blood (Table 129-1). These disorders may range from mild and transient to chronic and life-threatening, and, importantly, blood eosinophil numbers do not always reflect the extent of eosinophil involvement in disease-affected tissues. Because prolonged eosinophilia is associated with end-organ damage, especially involving the heart, patients with persistently elevated AECs should undergo a thorough evaluation to search for an underlying cause.

Allergic Diseases
Allergy is the most common cause of eosinophilia in children in the United States. Patients with allergic asthma commonly have eosinophils in the blood, sputum, and/or lung tissue. Hypersensitivity drug reactions can elicit eosinophilia, and when associated with organ dysfunction (e.g., DRESS [drug rash with eosinophilia and systemic symptoms]), these reactions can be serious (see Chapter 152). If a drug is suspected of triggering eosinophilia, biochemical evidence of organ dysfunction should be sought and if found, the drug should be discontinued. Various skin diseases have also been associated with eosinophilia, including atopic dermatitis/eczema, pemphigus, urticaria, and toxic epidermal necrolysis.
Causes of Eosinophilia

Eosinophils are a type of white blood cell that play a role in immune responses and inflammatory processes. They are involved in the defense against parasites and allergic reactions, and their presence in the body can indicate a range of conditions.

**ALLERGIC DISORDERS**
- Allergic rhinitis
- Asthma
- Acute and chronic urticaria
- Pemphigoid
- Hypersensitivity drug reactions (drug rash with eosinophilia and systemic symptoms [DRESS])
- Eosinophilic gastrointestinal disorders
- Intestinal neoplasms

**INFECTIOUS DISEASES**
- Tissue-Invasive Helminth Infections
  - Trichinosis
  - Toxocariasis
  - Strongyloidosis
  - Ascaris
  - Filariasis
  - Schistosomiasis
  - Echinococcosis
  - Pneumocystis carinii
- Toxoplasmosis
- Scarlet fever
- Amebiasis
- Malaria
- Bronchopulmonary aspergillosis
- Coccidioidomycosis
- Scabies

**MALIGNANT DISORDERS**
- Brain tumors
- Hodgkin disease and T-cell lymphoma
- Acute myelogenous leukemia
- Myeloproliferative disorders
- Eosinophilic leukemia

**GASTROINTESTINAL DISORDERS**
- Inflammatory bowel disease
- Peritoneal dialysis
- Chronic active hepatitis
- Eosinophilic gastrointestinal disorders:
  - Eosinophilic esophagitis
  - Eosinophilic gastroenteritis
  - Eosinophilic colitis

**RHEUMATOLOGIC DISEASE**
- Rheumatoid arthritis
- Eosinophilic fasciitis
- Scleroderma

**IMMUNODEFICIENCY DISEASE**
- Hyperimmunoglobulin E syndromes
- Wiskott-Aldrich syndrome
- Graft-versus-host disease
- Omenn syndrome
- Severe congenital neutropenia
- Hypersensitivity pneumonia

**MISCELLANEOUS**
- Thrombocytopenia with absent radii
- Churg-Strauss syndrome (eosinophilic granulomatosis with vasculitis)
- Vasculitis
- Adrenal insufficiency
- Postirradiation of abdomen
- Histiocytosis with cutaneous involvement
- Hypereosinophilic syndromes
- Autoimmune lymphoproliferative syndromes (ALPS)
- Immune dysregulation, polyendocrinopathy, X-linked (IPEX)

**Hypereosinophilic Syndrome**

The idiopathic hypereosinophilic syndrome is a heterogeneous group of disorders characterized by sustained overproduction of eosinophils. The 3 diagnostic criteria for this disorder are (1) AEC >1,500 cells/µL persisting for 6 mo or longer or at least on 2 occasions or with evidence of tissue eosinophilia; (2) absence of another diagnosis to explain the eosinophilia; and (3) signs and symptoms of organ involvement. The clinical signs and symptoms of hypereosinophilic syndrome can be heterogeneous because of the diversity of potential organ (pulmonary, cutaneous, neurologic, serosal, gastrointestinal) involvement. Loeﬄer endocarditis, one of the most serious and life-threatening complications, can cause heart failure from endomyocardial thrombosis and ﬁbrosis. Eosinophilic leukemia, a clonal myeloproliferative variant, may be distinguished from idiopathic hypereosinophilic syndrome by demonstrating a clonal interstitial deletion on chromosome 4q12 that fuses the platelet-derived growth factor receptor-α (PDGFRA) and FIP1-like-1 (FIP1L1) genes; this disorder is treated with imatinib mesylate, which helps target the fusion oncoprotein (Fig. 129-1).

Therapy is aimed at suppressing eosinophilia and is initiated with corticosteroids. Imatinib mesylate, a tyrosine kinase inhibitor, may be effective in FIP1L1-PDGFRα-negative patients. Hydroxyurea may be beneficial in patients unresponsive to corticosteroids. Specific antischistosome antibodies (mebendazole) target this cytokine, which has a central role in eosinophil differentiation, mobilization and activity. With therapy, the eosinophil count declines and corticosteroid doses may be reduced. For patients with prominent organ involvement who fail to respond to therapy, the mortality is ≈75% after 3 yr.

**Miscellaneous Diseases**

Eosinophilia is observed in many patients with primary immunodeﬁciency syndromes, especially hyperimmunoglobulin E syndrome (see Chapters 122 and 126), Wiskott-Aldrich syndrome, and Omenn syndrome. Eosinophilia is also frequently present in the syndrome of thrombocytopenia with absent radii and in familial diseases, such as melanoma, Merkel cell carcinoma, and chronic granulomatous disease.
reticuloendotheliosis with eosinophilia. Eosinophilia can be found in patients with Hodgkin disease, as well as in acute lymphoid and myeloid leukemia. Other considerations include gastrointestinal disorders such as ulcerative colitis, Crohn disease during symptomatic phases, chronic hepatitis, Churg-Strauss vasculitis, and adrenal insufficiency.

Bibliography is available at Expert Consult.

Figure 129-1 Revised classification of hypereosinophilic syndromes. Changes from the previous classification are indicated in red. Dashed arrows identify hypereosinophilic syndrome (HES) forms for which at least some patients have T-cell–driven disease. Classification of myeloproliferative forms has been simplified, and patients with HES and eosinophil hematopoietin–producing T cells in the absence of a T-cell clone are included in the lymphocytic forms of HES. IBD, Inflammatory bowel disease. (From Simon HU, Rothenberg ME, Bocher BS, et al: Refining the definition of hypereosinophilic syndrome. J Allergy Clin Immunol 126:45–49, 2010, Fig. 1, p. 47.)

Disorders of Phagocyte Function
Thomas D. Coates

Neutrophils are the first-line of defense against microbial invasion. They arrive at the site of inflammation during the critical 2-4 hr after microbial invasion to contain the infection and prevent hematogenous dissemination. This well-orchestrated process is one of the most interesting stories in modern cell biology. In fact, much of our knowledge about neutrophil function derives from studies done in patients with genetic errors in neutrophil function. These critical functions and their associated disorders are depicted in Figure 127-2. Children with phagocytic dysfunction present at a young age with recurrent infections that are often involve unusual organisms and are poorly responsive to treatment.

Primary defects of phagocytic function comprise fewer than 20% of immunodeficiencies and there is significant overlap in the presenting signs and symptoms between phagocytic disorders and lymphocyte and humeral disorders. Children with phagocytic defects present with deep tissue infection, pneumonia, adenitis, or osteomyelitis rather than blood stream infections (Tables 130-1 and 130-2, and Fig. 130-1). A few clinical features point to phagocyte defects rather than other immunodeficiencies, but correct diagnosis relies on highly specialized laboratory tests.

Chemotaxis, the direct migration of cells into sites of infection, involves a complex series of events (see Chapter 127). Disorders of adhesion or granule abnormalities can have intermediate or profound motility defects and the propensity to infections is related to a combination of these functional deficits. However, studies of a Tongan family with recessively inherited neutrophil actin dysfunction tell us that a pure severe chemotactic defect can result in fatal recurrent infection. Defective in vitro chemotaxis of neutrophils can be detected in children having various clinical conditions. However, unless chemotaxis is essentially absent, it is difficult to establish whether frequent infections arise from a primary chemotactic abnormality or occur as secondary medical complications of the underlying disorder. For example, dental infection with Capnocytophaga is associated with a clear neutrophil motility defect that resolves when the infection is eliminated.

Motility defects present with significant skin and mucosal infections. They can also have tender cutaneous nodular lesions that characteristically do not contain any neutrophils. In fact, presence of a true abscess makes the diagnosis of a significant chemotactic defect less likely.

Laboratory tests of chemotaxis are biologic assays and have high variability except in the most experienced of hands. The assays must be done on freshly obtained blood and are affected by many factors related to blood sampling itself. It is best to assay other features of the suspected disorder, such as surface marker expression, to establish a specific diagnosis.

LEUKOCYTE ADHESION DEFICIENCY
Leukocyte adhesion deficiency 1 (LAD-1), 2 (LAD-2), and 3 (LAD-3) are rare autosomal recessive disorders of leukocyte function. LAD-1 affects about 1 per 10 million individuals and is characterized by

recurrent bacterial and fungal infections and depressed inflammatory responses despite striking blood neutrophilia (Table 130-3). The neutrophils have significant defects in adhesion, motility, and ability to phagocytose bacteria.

**Genetics and Pathogenesis**

**LAD-1** results from mutations of the gene on chromosome 21q22.3 encoding CD18, the 95-kDa β2-leukocyte transmembrane integrin subunit. Normal neutrophils express 4 heterodimeric adhesion molecules: LFA-1 (CD11a/CD18), Mac-1 (CD11b/CD18), p150,95 (CD11c/CD18), and α4β1 (CD11d/CD18). These 4 transmembrane adhesion molecules are composed of unique extracellular α and β subunits (CD18) that links them to the membrane and connects them to intracellular signal transduction machinery. This group of leukocyte integrins is responsible for the tight adhesion of neutrophils to the endothelial cell surface, egress from the circulation, and adhesion to iC3b-coated microorganisms, which promotes phagocytosis and particulate activation of the phagocyte nicotinamide adenine dinucleotide phosphate (NADPH) oxidase. Some mutations of CD11/CD18 allow a low level of assembly and activity of integrin molecules, resulting in retention of some neutrophil integrin adhesion function and a moderate phenotype.

Because of their inability to adhere firmly to intercellular adhesion molecules 1 (ICAM-1) and 2 (ICAM-2) expressed on inflamed endothelial cells (see Chapter 127), neutrophils cannot transmigrate through the vessel wall and move to the site infection. Furthermore, neutrophils that do arrive at inflammatory sites fail to recognize microorganisms opsonized with complement fragment iC3b, an important stable opsonin formed by the cleavage of C3b. Hence, other neutrophil functions, such as degranulation and oxidative metabolism normally triggered by iC3b binding are also markedly compromised in LAD-1 neutrophils, resulting in impaired phagocytic function and high risk for serious and recurrent bacterial infections.

Monocyte function is also impaired, with poor fibrinogen-binding function, an activity that is promoted by the CD11/CD18 complex. Consequently, such cells are unable to participate effectively in wound healing.

OMIM, Online Mendelian Inheritance in Man.

Children with LAD-2 share the clinical features of LAD-1 but have normal CD11/CD18 integrins. Features unique to LAD-2 include neurologic defects, cranial facial dysmorphism, and absence of the erythrocyte ABO blood group antigen (Bombay phenotype). LAD-2 (also known as congenital disorder of glycosylation IIc) derives from mutations in the gene encoding a specific GDP-L-fucose transporter of the Golgi apparatus. This abnormality prevents the incorporation of fucose into various cell surface glycoproteins, including the carbohydrate structure sialyl Lewis X that is critical for low-affinity rolling adhesion of neutrophils to vascular endothelium. This is an important initial step necessary for subsequent integrin-mediated activation, spreading, and transendothelial migration. Infections in LAD-2 are milder than that in LAD-1.

LAD-3 is characterized by a Glanzmann thrombasthenia-like bleeding disorder, delayed separation of the umbilical cord, and serious skin and soft-tissue infections similar to that seen in LAD-1, and failure of leukocytes to undergo β2- and β1-integrin–mediated adhesion and migration. Mutations in KINDLIN3 affect integrin activation.

### Clinical Manifestations

Patients with the severe clinical form of LAD-1 express <0.3% of the normal amount of the β2-integrin molecules, whereas patients with the moderate phenotype may express 2-7% of the normal amount. Children with severe forms of LAD present in infancy with recurrent, indolent bacterial infections of the skin, mouth, respiratory tract, lower intestinal tract, and genital mucosa. Significant neutrophilic leukocytosis, often >25,000/µm³, is a prominent feature. They may have a history of delayed separation of the umbilical cord, usually with associated infection of the cord stump. The presence of significant omphalitis is an important feature that distinguishes these rare patients from the 10% of healthy infants who can have cord separation at age 3 wk or later. Skin infection may progress to large chronic ulcers with polymicrobial infection, including anaerobic organisms (Fig. 130-2). The ulcers heal slowly, need months of antibiotic treatment, and often require plastic surgery grafting. Severe gingivitis can lead to early loss of primary and secondary teeth (Fig. 130-3). Infected areas characteristically have very little neutrophil infiltration.

The pathogens infecting patients with LAD-1 are similar to those affecting patients with severe neutropenia (see Chapter 131) and include *Staphylococcus aureus* and enteric Gram-negative organisms such as *Escherichia coli*. These patients are also susceptible to opportunistic infection by fungi such as *Candida* and *Aspergillus*. Typical signs of inflammation, such as swelling, erythema, and warmth, may be absent. Pus does not form, and few neutrophils are identified microscopically in biopsy specimens of infected tissues. Despite the paucity of neutrophils within the affected tissue, the circulating neutrophil count during infection typically exceeds 30,000/µL and can surpass 100,000/µL. During intervals between infections, the peripheral blood neutrophil count may chronically exceed 12,000/µL. LAD-1 genotypes with only moderate, rather than absent, amounts of functional integrins at the surface of the neutrophil, significantly have reduced severity and frequency of infections compared to children with the severe form, although gingival disease is still a prominent feature.

### Laboratory Findings

The diagnosis of LAD-1 is established most readily by flow cytometric measurements of surface CD11b/CD18 in stimulated and unstimulated neutrophils. Neutrophil and monocyte adherence, aggregation, chemotaxis, and iC3b-mediated phagocytosis demonstrate striking abnormalities. However, these assays are not clinically available. Delayed-type hypersensitivity reactions are normal, and most individuals have normal specific antibody synthesis. However, some patients have impaired T-lymphocyte–dependent antibody responses. The diagnosis of LAD-2 is established by flow cytometric measurement of sialyl Lewis X (CD15) on neutrophils. It is important to note that the flow cytometric assays are not done the same as the more common lymphocyte subset analysis and require specialized approaches to detect levels of surface expression, especially to detect milder phenotypes.

### Treatment

Treatment of LAD-1 depends on the phenotype as determined by the level of expression of functional CD11/CD18 integrins. Early allogeneic hematopoietic stem cell transplantation (HSCT) is the treatment of choice for severe LAD-1 (and LAD-3). Other treatment is largely supportive. Patients can be maintained on prophylactic trimethoprim-sulfamethoxazole and should have close surveillance for early identification of infections and initiation of empirical treatment with broad-spectrum antibiotics. Specific determination of the etiologic agent by culture or biopsy is important because of the prolonged antibiotic treatment required in the absence of neutrophil function. Some LAD-2 patients have responded to fucose supplementation, which induced a rapid reduction in the circulating leukocyte count and appearance of the sialyl Lewis X molecules accompanied by marked improvement in leukocyte adhesion.

### Prognosis

The severity of infectious complications correlates with the degree of β2-integrin deficiency. Patients with severe deficiency may die in infancy, and those surviving infancy have a susceptibility to severe life-threatening systemic infections. Patients with moderate deficiency have infrequent life-threatening infections and relatively long survival.

---

**Figure 130-2** Skin infection of a patient with leukocyte adhesion deficiency type 1. Failure to form pus, inability to demarcate the fibrotic skin debris, and limited inflammation. Enterococcus gallinarium was cultured from the wound. (From Rich RR: Clinical immunology principles and practices, ed 4, Philadelphia, 2013, WB Saunders, Fig. 21-3, p. 273.)

**Figure 130-3** Oral pathology in a patient with leukocyte adhesion deficiency type 1. Gingivitis and severe periodontitis are hallmarks of LAD 1. (From Rich RR: Clinical immunology principles and practices, ed 4, Philadelphia, 2013, WB Saunders, Fig. 21-2, p. 273.)
Chapter 130  Disorders of Phagocyte Function 1045

CHÉDIAK-HIGASHI SYNDROME

Chédiak–Higashi syndrome (CHS) is a rare autosomal recessive disorder characterized by increased susceptibility to infection caused by defective degranulation of neutrophils, a mild bleeding diathesis, partial oculocutaneous albinism, progressive peripheral neuropathy, and a tendency to develop a life-threatening form of hemophagocytic lymphohistiocytosis (see Chapter 507). CHS is caused by a fundamental defect in granule morphogenesis that results in abnormally large granules in multiple tissues. Pigmentary dilution involving the hair, skin, and ocular fundi results from pathologic aggregation of lysosomes. Neurologic deficits are associated with a failure of degranulation of the optic and auditory nerves. Patients exhibit an increased susceptibility to infection that can be explained only in part by defects in neutrophil function. The patients have progressive neutropenia as well as abnormalities in natural killer (NK) function, again related to granule dysfunction.

Genetics and Pathogenesis

LYST (for lysosomal traffic regulator), the gene mutated in CHS, is located at chromosome 1q2-q44. The LYST/CHS protein is thought to regulate vesicle transport by mediating protein–protein interaction and protein–membrane associations. Loss of function may lead to indiscriminate interactions with lysosomal surface proteins, yielding giant granules through uncontrolled fusion of lysosomes with each other.

Almost all cells of patients with CHS show some oversized and dysmorphic lysosomes, storage granules, or related vesicular structures. Melanosomes are oversized, and delivery to the keratinocytes and hair follicles is compromised, resulting in hair shafts devoid of pigment granules. This abnormality in melanosomes leads to the macroscopic impression of hair and skin that is lighter than expected from parental coloration. The same abnormality in melanosomes leads to the partial ocular albinism associated with light sensitivity.

Beginning early in neutrophil development, spontaneous fusion of giant primary granules with each other or with cytoplasmic membrane components results in huge secondary lysosomes with reduced contents of hydrolytic enzymes, including proteinases, elastase, and cathepsin G. This deficiency of proteolytic enzymes may be responsible for the impaired killing of microorganisms by CHS neutrophils.

Clinical Manifestations

Patients with CHS have light skin and silvery hair and frequently complain of solar sensitivity and photophobia that is associated with rotary nystagmus. Other signs and symptoms vary considerably, but frequent infections and neuropathy are common. The infections involve mucous membranes, skin, and respiratory tract. Affected children are susceptible to Gram-positive bacteria, Gram-negative bacteria, and fungi, with S. aureus being the most common offending organism. The neuropathy may be sensory or motor in type, and ataxia may be a prominent feature. Neuropathy often begins in the teenage years and becomes the most prominent problem.

Patients with CHS have prolonged bleeding times with normal platelet counts, resulting from impaired platelet aggregation associated with a deficiency of the dense granules containing adenosine diphosphate and serotonin.

The most life-threatening complication of CHS is the development of an accelerated phase characterized by pancytopenia, high fever, and lymphohistiocytic infiltration of liver, spleen, and lymph nodes. The onset of the accelerated phase, which can occur at any age, is now recognized to be a genetic form of hemophagocytic lymphohistiocytosis. This occurs in 85% of patients and usually results in death.

Laboratory Findings

The diagnosis of CHS is established by finding large inclusions in all nucleated blood cells. These can be seen on Wright-stained blood films and are accentuated by a peroxidase stain. Because of impaired egress from the bone marrow, cells containing the large inclusions may be missed on peripheral blood smear but readily identified on bone marrow examination. The patients have progressive neutropenia and abnormal platelet, neutrophil, and NK function.

Treatment

High-dose ascorbic acid (200 mg/day for infants, 2,000 mg/day for adults) may improve the clinical status of some children in the stable phase. Although controversy surrounds the efficacy of ascorbic acid, given the safety of the vitamin, it is reasonable to administer ascorbic acid to all patients.

The only curative therapy to prevent the accelerated phase is HSCT. Normal stem cells reconstitute hematopoietic and immunologic function, correct the NK cell deficiency, and prevent conversion to the accelerated phase, but cannot correct or prevent the neuropathy. If the patient is in the accelerated phase with active hemophagocytic lymphohistiocytosis, HSCT often fails to prevent death.

MYELOPEROXIDASE DEFICIENCY

Myeloperoxidase (MPO) deficiency is an autosomal recessive disorder of oxidative metabolism and is one of the most common inherited disorders of phagocytes, occurring at a frequency approaching 1 per 2,000 individuals. MPO is a green heme protein located in the azurophilic lysosomes of neutrophils and monocytes and is the basis for the greenish tinge to pus accumulated at a site of infection.

Clinical Manifestations

MPO deficiency is usually clinically silent. Rarely, patients may have disseminated candidiasis, usually in conjunction with diabetes mellitus. Acquired partial MPO deficiency can develop in acute myelogenous leukemia and in myelodysplastic syndromes.

Laboratory Findings

Deficiency of neutrophil and monocyte MPO can be identified by histochemical analysis. Severe MPO deficiency can cause the dihydroorhodamine (DHR) flow cytometric assay for chronic granulomatous disease to be falsely positive. Unlike chronic granulomatous disease (CGD), eosinophils in severe MPO deficiency will still reduce DHR and yield a normal reaction.

Treatment

There is no specific therapy. Aggressive treatment with antifungal agents should be provided for candidal infections. The prognosis is usually excellent.

CHRONIC GRANULOMATOUS DISEASE

CGD is characterized by neutrophils and monocytes capable of normal chemotaxis, ingestion, and degranulation, but unable to kill catalase-positive microorganisms because of a defect in the generation of microbicidal oxygen metabolites. CGD is a rare disease with an incidence of 4-5 per 1 million individuals; it is caused by 4 genes, 1 X-linked and 3 autosomal recessive in inheritance.

Genetics and Pathogenesis

Activation of the phagocyte NADPH oxidase requires stimulation of the neutrophils and involves assembly from cytoplasmic and integral membrane subunits (see Fig. 127-3). Oxidase activation initiates with phosphorylation of a cationic cytoplasmic protein, p47phox (47-kDa phagocyte oxidase protein). Phosphorylated p47phox, together with 2 other cytoplasmic components of the oxidase, p67phox and the low-molecular-weight guanosine triphosphatase Rac2, translocates to the membrane where they combine with the cytoplasmic domains of the transmembrane flavocytochrome b558 to form the active oxidase complex (see Fig. 127-3). The flavocytochrome is a heterodimer composed of p22phox and highly glycosylated gp91phox. The gp91phox glycoprotein catalyzes electron transport through its NADPH-binding, flavin-binding, and heme-binding domains. Defects in any of these NADPH oxidase components can lead to CGD.

Approximately 65% of patients with CGD are males who inherit their disorder as a result of mutations in CYBB, an X-chromosome gene encoding gp91phox. Approximately 35% of patients inherit CGD in an autosomal recessive fashion resulting from mutations in the NCF1 gene on chromosome 7, encoding p47phox. Defects in the genes...
The pathogenesis of chronic granulomatous disease (CGD). The manner in which the metabolic deficiency of the CGD neutrophil predisposes the host to infection is shown schematically. Normal neutrophils stimulate hydrogen peroxide in the phagosome containing ingested Escherichia coli. Myeloperoxidase is delivered to the phagosome by degranulation, as indicated by the closed circles. In this setting, hydrogen peroxide acts as a substrate for myeloperoxidase to oxidize halide to hypochlorous acid and chloramines that kill the microbes. The quantity of hydrogen peroxide produced by the normal neutrophil is sufficient to exceed the capacity of catalase, a hydrogen peroxide-catabolizing enzyme of many aerobic microorganisms, including Staphylococcus aureus, most Gram-negative enteric bacteria, Candida albicans, and Aspergillus. When organisms such as E. coli gain entry into CGD neutrophils, they are not exposed to hydrogen peroxide because the neutrophils do not produce it, and the hydrogen peroxide generated by macroorganisms themselves is destroyed by their own catalase. When CGD neutrophils ingest streptococci, which lack catalase, the organisms generate enough hydrogen peroxide to result in a microbicidal effect. As indicated (middle), catalase-positive microbes such as E. coli can survive within the phagosome of the CGD neutrophil. (Modified from Boxer LA: Quantitative abnormalities of granulocytes. In Butler E, Lichtman MA, Coller BS, et al, editors: Williams hematology, ed 6, New York, 2001, McGraw-Hill, p. 845.)

Figure 130-4

Laboratory Findings

The diagnosis is most often made by performing flow cytometry using dihydrorhodamine 123 (DHR) to measure oxidant production through its increased fluorescence when oxidized by H2O2. The nitroblue tetrazolium dye test is frequently cited in the literature but is now rarely used clinically. The X-linked carrier state is usually easily diagnosed in the mother by DHR fluorescence by presence of a bimodal response to stimulation. It is important to test the mother as some extremely Lyonized carriers with <5% positive cells may have chronic clinical problems as well. Ideally, at least the first patient in a kindred should have DNA analysis to facilitate prenatal diagnosis and for genetic counseling purposes.

A few individuals have been described with apparent CGD caused by severe glucose-6-phosphate dehydrogenase deficiency, leading to insufficient NADPH substrate for the phagocyte oxidase. The erythrocytes of these patients also lack the enzyme, leading to chronic hemolysis.

Treatment

HSCT is the only known cure for CGD, although gene therapy has been transiently successful in a few patients and is the topic of active research. We strongly recommend HSCT transplant for all patients with CGD if a suitable sibling or unrelated donor can be identified. The long-term outcome for survival late into adulthood is not good even in the hands of experienced CGD clinicians. Patients with CGD should be given daily oral trimethoprim-sulfamethoxazole as it reduces the number of bacterial infection. A placebo-controlled study found that interferon-γ 50 µg/m² 3 times/wk significantly reduces the number of hospitalizations and serious infections, although the mechanism of action is unclear. Itraconazole (200 mg/day for patients weighing >50 kg and 100 mg/day for patients weighing <50 kg and 5 yr of age or younger) administered prophylactically reduces the frequency of fungal infections.

Management of infection is dramatically different than in normal children. CGD patients are always at risk for deep-seated, indolent bacterial infections that can become widespread if not treated properly. They also develop the same kinds of infections that occur in normal children so determination of the appropriate treatment can be difficult. The erythrocyte sedimentation rate (ESR) can be quite helpful. If the child does not have a deep-seated infection, the ESR will be normal or will normalize within several days with standard management. However, if it does not, a search for deep tissues is warranted, as is consideration of empiric antibiotics. Cultures should be obtained, but are usually negative. Because all neutrophil functions in CGD except killing are normal, there is often an exuberant inflammatory reaction to a very small number of organisms. Thus, blood cultures and direct cultures of biopsy samples are usually negative unless there are a lot of organisms. Most abscesses require surgical drainage for therapeutic
and diagnostic purposes. Prolonged use of antibiotics is required even for common bacterial infections. A simple pneumonia may require 6-8 wk of parenteral antibiotics. Infections should be treated for at least 1 wk past normalization of the sedimentation rate to prevent recurrence. Severe pneumonias can be cleared completely but may require many months of parenteral antibiotics. Especially because cultures are often not helpful, we support an “antibiotic sensitivity by sedimentation rate response” approach to treatment. The ESR rates are often in the 40-80 mm/hr or more range with severe infection and will drop monotonically over a week or so after starting antibacterial drugs. It is important to check the ESR daily or every other day as there is moderate variability in this test and changes in treatment need to be based on trends rather than individual values. If there is a clear downward trend over 3-6 days, we continue with antibacterials alone. If this is not the case, parenteral voriconazole should be added to cover *Aspergillus*. Failure of the ESR to come down suggests another antimicrobial approach needs to be tried. Because of the rarity of this disorder, it is critical to seek counsel from someone with significant direct experience with management of several CGD patients. Granulocyte transfusions have been used but it is not clear that they are very helpful. The ESR should be regularly monitored in well patients and whenever they appear ill. A high ESR itself is usually not enough to trigger treatment. However, in the presence of symptoms, one should search for sources at least by contrast CT of the sinus, chest, and abdomen. If the patient is unstable or has very high fevers, *B. cepacia* should be considered and empirically covered. This organism can cause septic shock quickly, unlike the usual smoldering infections seen in CGD. We treat with antibiotics until the ESR is normal and radiographic evidence of infection has been cleared, if possible. The overall incidence of infection decreases in the second decade of life as nonneutrophil immunity matures, but increased risk of infection is lifelong.

Corticosteroids may be useful for the treatment of children with antral and urethral obstruction or severe granulomatous colitis. They can also be helpful in pneumonia to shrink granulomas in the lung and promote drainage. We favor short (4-6 days) pulses of 1-2 mg/kg prednisone with rapid taper to avoid long-term side effects and risk of fungus. Pulses can be repeated if clinical effect has not been achieved.

**Genetic Counseling**

Identifying a patient’s specific genetic subgroup by DNA analysis is useful primarily for genetic counseling and prenatal diagnosis. In X-linked CGD, all possibly affected females should be tested by DHR to exclude carrier state. Counseling is best done by a physician who has direct knowledge of the clinical manifestations of CGD.

**Prognosis**

The overall mortality rate for CGD is about 2 patient deaths/yr per 100 cases, with the highest mortality among young children. The development of effective infection prophylactic regimens, close surveillance for signs of infections, and aggressive surgical and medical interventions has improved the prognosis.

Chapter 131  Leukopenia
Kelly J. Walkovich and Peter E. Newburger

Leukopenia refers to an abnormally low number of white blood cells (WBCs) in the circulating blood secondary to a paucity of lymphocytes, granulocytes or both. Because there are marked developmental changes in normal values for WBC counts during childhood (see Chapter 727), normal ranges must be considered in the context of age.

For newborns, the mean WBC count at birth is high, followed by a rapid fall beginning at 12 hr through the 1st wk of life. Thereafter, values are stable until 1 yr of age, after which a slow steady decline in the WBC count continues throughout childhood until adult values are reached during adolescence. Evaluation of patients with leukopenia begins with a thorough history, physical examination, and at least 1 confirmatory complete blood count with differential. Further evaluation then depends upon whether the leukopenia represents a decreased number of neutrophils, lymphocytes, or both cell populations (Table 131-1). Treatment depends upon the etiology and clinical manifestations of the leukopenia.

NEUTROPENIA
Neutropenia is defined as a decrease in the absolute number of circulating segmented neutrophils and bands in the peripheral blood. The absolute neutrophil count (ANC) is determined by multiplying the total WBC count by the percentage of segmented neutrophils plus bands. Normal neutrophil counts must be stratified for age and race. Neutrophils predominate at birth but rapidly decrease in the 1st few days of life. During infancy, neutrophils constitute 20-30% of circulating leukocyte populations. Near equal numbers of neutrophils and lymphocytes are found in the peripheral circulation at 5 yr of age, and the characteristic 70% predominance of neutrophils that occurs in adulthood is usually attained during puberty. For white children older than 12 mo of age, the lower limit of normal for the ANC is 1,500/µL; for black children older than 12 mo of age the lower limit of normal is 1,200/µL. The relatively lower limit of normal in blacks likely reflects the prevalence of the Duffy negative (Fy−/−) blood group, which is selectively enriched in populations in the malarial belt of Africa and is associated with ANCs 200-600/µL less than those who are Duffy positive.

Neutropenia may be characterized as mild neutropenia, with an ANC of 1,000-1,500/µL; moderate neutropenia, with an ANC of 500-1,000/µL; or severe neutropenia, with an ANC <500/µL. ANC <200 is also termed agranulocytosis. This stratification aids in predicting the risk of pyogenic infection in patients who have neutropenia as a resulting from disorders of bone marrow production as only patients with severe neutropenia have a significantly increased susceptibility to life-threatening infections. Neutropenia associated with monocytopenia, lymphocytopenia, or hypogammaglobulinemia increases the risk for infection compared to isolated neutropenia. Patients with neutropenia caused by increased destruction (e.g., autoimmune) may tolerate very low ANCs without increased frequency of infection.

Acute neutropenia evolves over a few days and is often a result of rapid neutrophil use and/or compromised neutrophil production. Chronic neutropenia by definition lasts longer than 3 mo and arises from reduced production, increased destruction or excessive splenic sequestration of neutrophils. The etiology of neutropenia can be classified as either an acquired disorder or extrinsic insult (Table 131-2), or, more rarely, an inherited, intrinsic defect (Table 131-3).

Clinical Manifestations of Neutropenia
Individuals with neutrophil counts <500/µL are at substantial risk for developing infections, primarily from their endogenous flora as well as from nosocomial organisms. However, some patients with isolated chronic neutropenia may not experience many serious infections, probably because the remainder of the immune system remains intact or because neutrophil delivery to tissues is preserved, as in autoimmune neutropenias. In contrast, children whose neutropenia is secondary to acquired disorders of production such as with cytotoxic therapy, immunosuppressive drugs, or radiation therapy are likely to develop serious bacterial infections because many arms of the immune system are markedly compromised. Neutropenia associated with additional monocytopenia or lymphocytopenia, is more highly associated with serious infection than neutropenia alone. The integrity of skin and mucous membranes, the vascular supply to tissues, and nutritional status also influence the risk of infection.

The most common clinical presentation of profound neutropenia includes fever, aphthous stomatitis, and gingivitis. Infections
commonly associated with neutropenia include cellulitis, furunculosis, perirectal inflammation, colitis, sinusitis, and otitis media, as well as more serious infections such as pneumonia, deep tissue abscess, and sepsis. The most common pathogens causing infections in neutropenic patients are *Staphylococcus aureus* and Gram-negative bacteria. Isolated neutropenia does not heighten a patient’s susceptibility to parasitic or viral infections or to bacterial meningitis. The usual signs and symptoms of local infection and inflammation such as exudate, fluctuance, and regional lymphadenopathy may be diminished in the absence of neutrophils because of the inability to form pus, but patients with agranulocytosis still experience fever and feel pain at sites of inflammation.

### Laboratory Findings

Isolated absolute neutropenia has a limited number of causes (Tables 131-2 through 131-5). The duration and severity of the neutropenia greatly influence the extent of laboratory evaluation. Patients with chronic neutropenia since infancy and a history of recurrent fevers and chronic gingivitis should have WBC counts and differential counts determined 3 times/wk for 6-8 wk to evaluate the periodicity suggestive of cyclic neutropenia. Bone marrow aspiration and biopsy should be performed on select patients to assess cellularity and myeloid maturation. Additional marrow studies such as cytogenetic analysis and special stains for detecting leukemia and other malignant disorders should be obtained for patients with suspected intrinsic defects in the myeloid progenitors and for patients with suspected malignancy. If malignancy is not a concern, assessing the ANC before and 4-6 hr after a single dose of glucocorticosteroid (usually prednisone 1-2 mg/kg) measures mobilization of the bone marrow reserve pool of mature neutrophils; an increase in the ANC to a normal or only moderately low level indicates “chronic benign” or idiopathic neutropenia, and may render bone marrow examination unnecessary. Selection of further laboratory tests is determined by the duration and severity of the neutropenia and the associated findings on physical examination (see Table 131-1).

### Acquired Neutropenia

**Infection-Related Neutropenia.** Transient neutropenia often accompanies or follows viral infections (see Table 131-4) and is the most frequent cause of neutropenia in childhood. Viruses commonly causing acute neutropenia include influenzas A and B, adenovirus, respiratory syncytial virus, enteroviruses, human herpes virus 6, measles, rubella, and varicella. Parvovirus B19 and hepatitides A and B may also cause neutropenia, but are more commonly associated with pure red cell aplasia or multiple cytopenias, respectively. Viral-associated acute neutropenia often occurs during the 1st 24-48 hr of illness and usually persists for 3-8 days, which generally corresponds to the period of viremia. The neutropenia is related to virus-induced redistribution of neutrophils from the circulating to the marginating pool. In addition, neutrophil sequestration may occur after virus-induced tissue damage or splenomegaly. Significant neutropenia also may be associated with severe bacterial, protozoal, rickettsial, and fungal infections (see Table 131-4). Bacterial sepsis is a particularly serious cause of neutropenia, especially among younger infants and

children. Premature neonates are especially prone to exhausting their marrow reserve and rapidly succumbing to bacterial sepsis.

Chronic neutropenia often accompanies infection with Epstein-Barr virus, cytomegalovirus, or HIV. The neutropenia associated with AIDS probably arises from a combination of viral bone marrow suppression, antibody-mediated destruction of neutrophils, and effects of antiretroviral or other drugs.

**Drug-Induced Neutropenia.** Drugs constitute a common cause of neutropenia (see Table 131-5). The incidence of drug-induced neutropenia peaks dramatically with age; only 10% of cases occur among children and young adults. The majority of cases occur among adults older than age 65 yr, likely reflecting the more frequent use of multiple medications in that age group. Almost any drug can cause neutropenia. The most common offending drug classes are antimicrobial agents, antithyroid drugs, antipsychotics, antipyretics, and antirheumatics. Drug-induced neutropenia has several underlying mechanisms—immune-mediated, toxic, idiosyncratic, hypersensitivity, idiopathic—that are distinct from the severe neutropenia that predictably occurs after administration of antineoplastic drugs or radiotherapy.

Drug-induced neutropenia from immune mechanisms usually develops abruptly, is accompanied by fever, and lasts for about 1 wk after the discontinuation of the drug. The process likely arises from effects of drugs, such as propylthiouracil or penicillin, that act as haptons to stimulate antibody formation, or drugs, such as quinine, that induce immune complex formation. Other drugs, including the antipsychotic drugs such as the phenothiazines, can cause neutropenia when given in toxic amounts, but some individuals, such as those with preexisting neutropenia, may be susceptible to levels at the high end of the usual therapeutic range. Late-onset neutropenia can occur after rituximab therapy. Idiosyncratic reactions, for example to chloramphenicol, are unpredictable with regard to dose or duration of use. Hypersensitivity reactions are rare and may involve arene oxide metabolites of aromatic anticonvulsants. Fever, rash, lymphadenopathy, hepatitis, nephritis, pneumonitis, and aplastic anaemia are often associated with hypersensitivity-induced neutropenia. Acute hypersensitivity reactions such as those caused by phenytoin or phenobarbital may last for only a few days if the offending drug is discontinued. Chronic hypersensitivity may last for months to years.

Once neutropenia occurs, the most effective therapeutic measure is withdrawal of nonessential drugs, particularly drugs most commonly associated with neutropenia. Usually the neutropenia will resolve soon after withdrawal of the offending drug. If the neutropenia fails to improve with drug withdrawal and the patient is symptomatic with infection or stomatitis, subcutaneous administration of recombinant human granulocyte colony-stimulating factor (filgrastim) 5 μg/kg/day should be considered. Drug-induced neutropenia may be asymptomatic and noted only as an incidental finding or because of regular monitoring of WBC counts during drug therapy. For patients who are asymptomatic, continuation of the suspected offending drug depends on the relative risks of neutropenia vs discontinuation of a possibly essential drug. If the drug is continued, blood counts should be monitored for possible progression to agranulocytosis.

Neutropenia commonly and predictably follows the use of antancer drugs or radiation therapy, especially radiation therapy directed at the pelvis or vertebrae, secondary to cytotoxic effects on rapidly replicating myeloid precursors. A decline in the WBC count typically occurs 7-10 days after administration of the anticancer drug and may persist for 1-2 wk. The neutropenia accompanying malignancy or following cancer chemotherapy is frequently associated with compromised cellular immunity and barrier compromise secondary to central venous lines and mucositis, thereby predisposing patients to a much greater risk of infection (see Chapter 178) than found in disorders associated with isolated neutropenia. Patients with chemotherapy/radiation-related neutropenia and fever must be treated aggressively with broad-spectrum antibiotics.

**Nutrition-Related Neutropenia.** Poor nutrition can contribute to neutropenia. Ineffective myelopoiesis may result in neutropenia caused by acquired dietary vitamin B₁₂ or folic acid deficiency. In addition, megaloblastic pancytopenia also can result from extended use of antibiotics such as trimethoprim-sulfamethoxazole, which inhibit folic acid metabolism, and from the use of phenytoin, which may impair folate absorption in the small intestine, or from surgical resection of the small intestine. Neutropenia also occurs with starvation and marasmus in infants, with anorexia nervosa, and occasionally among patients receiving prolonged parenteral nutrition without vitamin supplementation.

**Immune-Mediated Neutropenia.** Immune-mediated neutropenia is usually associated with the presence of circulating antineutrophil antibodies, which may mediate neutrophil destruction by complement-mediated lysis or splenic phagocytosis of opsonized neutrophils, or by accelerated apoptosis of mature neutrophils or myeloid precursors.

**Alloimmune neonatal neutropenia** occurs after transplacental transfer of maternal alloantibodies directed against antigens on the infant's neutrophils, analogous to Rh hemolytic disease. Prenatal sensitization induces maternal IgG antibodies to neutrophil antigens on fetal cells. The neutropenia is often severe and infants may present within the 1st 2 wk of life with skin or umbilical infections, fever, and pneumonia caused by the usual microbes that cause neonatal disease. By 7 wk of age, the neutrophil count usually returns to normal, reflecting the decay of maternal antibodies in the infant's circulation. Treatment consists of supportive care and appropriate antibiotics for clinical infections, plus filgrastim for severe infections without neutrophil recovery.

Mothers with autoimmune disease may give birth to infants who develop transient neutropenia, known as [neonatal passive autoimmune neutropenia](#). The duration of the neutropenia depends on the time required for the infant to clear the maternally transferred circulating immunoglobulin G antibody. It persists in most cases for a few weeks to a few months. Neonates almost always remain asymptomatic.

**Autoimmune neutropenia (AIN) of infancy** is a benign condition with an annual incidence of approximately 1 per 100,000 among children between infancy and 10 yr of age. Patients usually have severe neutropenia on presentation, with ANC <500/μL, but the total WBC count is generally within normal limits. Monocytosis or eosinophilia may occur but does not impact the low rate of infection. The median age of presentation is 8-11 mo with a range of 2-54 mo. There is a slight female predominance. The diagnosis is often evident when a blood count incidentally reveals neutropenia in a child with a minor infection. Occasionally, children may present with more severe infections, including abscesses, pneumonia, or sepsis. The diagnosis may be established by the presence of antineutrophil antibodies in serum; however, the test has frequent false-negative and false-positive results, so the absence of detectable antibodies does not exclude the diagnosis and a positive result does not extend other conditions. The diagnosis may also be based clinically on a benign course and normal or hyperplastic myeloid maturation in the bone marrow. There is considerable overlap between AIN of infancy and "chronic benign neutropenia.”

**Treatment** is not generally necessary because the disease is only rarely associated with severe infection and usually remits spontaneously. Low-dose filgrastim may be useful for severe infections, to promote wound healing following surgery, or to avert emergency room visits or hospitalizations for febrile illnesses. Longitudinal studies of infants with AIN demonstrate median durations of disease ranging from 7-30 mo. Affected children generally have no evidence or risk of other autoimmune diseases.

**AIN in older children** can occur as an isolated process, as a manifestation of other autoimmune diseases, or as a secondary complication of infection, drugs or malignancy. In primary AIN, low circulating neutrophil counts are the only hematologic finding, and associated diseases or other factors that cause neutropenia are absent. Secondary AIN associated with immune dysregulation or other factors is more commonly identified in older children and is less likely to spontaneously remit. AIN is distinguished from other forms of neutropenia by the demonstration of antineutrophil antibodies (with caveats discussed above) and myeloid hyperplasia on bone marrow examination. The
most common antineutrophil antibody targets are human neutrophil antigens 1a, 1b, and 2.

Treatment of AIN relies on management of any underlying disorders. In addition, judicious use of appropriate antibiotics for bacterial infections, and regular dental hygiene is generally beneficial. Infections tend to be less frequent in AIN than with the corresponding degree of neutropenia from other causes, probably because tissue delivery of neutrophils is greater than that in conditions resulting from impaired production. Prophylactic antibiotics may be helpful for the management of recurrent minor infections. For patients with serious or recurrent infections, filgrastim is generally effective at raising the ANC and preventing infection. Very low doses (<1-2 µg/kg/day) are usually effective, and administration of standard doses can lead to severe bone pain as a consequence of marrow expansion.

**Neutropenia Secondary to Bone Marrow Replacement.** Various acquired bone marrow disorders lead to neutropenia, usually accompanied by anemia and thrombocytopenia. Hematologic malignancies, including leukemia, lymphoma, and metastatic solid tumors suppress myelopoiesis by infiltrating the bone marrow with tumor cells. Neutropenia may also accompany aplastic anemia, myelodysplastic disorders or preleukemic syndromes, which are characterized by multiple cytopenias and often macrocytosis. Treatment requires management of the underlying disease.

**Neutropenia Secondary to Reticuloendothelial Sequestration.** Splenic enlargement resulting from intrinsic splenic disease (storage disease), portal hypertension, or systemic causes of splenic hyperplasia (inflammation or neoplasia) can lead to neutropenia. Most often the neutropenia is mild to moderate and is accompanied by corresponding degrees of thrombocytopenia and anemia. The reduced neutrophil survival corresponds to the size of the spleen, and the extent of the neutropenia is inversely proportional to bone marrow compensatory mechanisms. Usually the neutropenia may be corrected by successfully treating the underlying disease. In selected cases, splenectomy may be necessary to restore the neutrophil count to normal, but results in increased risk of infections by encapsulated bacterial organisms. Patients undergoing splenectomy should receive appropriate presplenectomy immunizations and may benefit from antibiotic prophylaxis postsplenectomy to help mitigate the risk of sepsis. Splenectomy should be avoided in patients with common variable immunodeficiency, autoimmune lymphoproliferative disease and other immunodeficiency syndromes because of the higher risk of sepsis.

**Inherited Neutropenia**

Intrinsic disorders of proliferation or maturation of myeloid precursor cells are rare. Table 131-6 presents a classification based on genetics and molecular mechanisms; selected disorders are discussed below.

**Primary Disorders of Granulopoiesis.** Cyclic neutropenia is a rare autosomal dominant congenital granulopoeitic disorder occurring with an estimated incidence of 0.5-1 cases per 1 million population. The disorder is characterized by regular, periodic oscillations, with the ANC ranging from normal to <200/µL, mirrored by reciprocal cycling of monocytes. Cyclic neutropenia is sometimes termed cyclic hematopoiesis because of the secondary cycling of other blood cells, such as platelets and reticulocytes. The mean oscillatory period of the cycle is 21 days (± 4 days). During the neutropenic nadir, many patients suffer from malaise, fever, oral and genital ulcers, gingivitis, periodontitis, or pharyngitis, and occasionally lymph node enlargement. More serious infections may occasionally occur, including pneumonia, mastoiditis, and intestinal perforation with peritonitis leading to life-threatening clostridial sepsis. Prior to the availability of filgrastim, approximately 10% of patients developed fatal clostridial or Gram-negative infections. Cyclic neutropenia arises from a regulatory abnormality involving early hematopoietic precursor cells and is almost invariably associated with mutations in the neutrophil elastase gene, ELANE, that lead to accelerated apoptosis as a result of abnormal protein folding. Many patients experience abatement of symptoms with age. The cycles tend to become less noticeable in older patients, and the hematologic picture often begins to resemble that of chronic idiopathic neutropenia.

Cyclic neutropenia is diagnosed by obtaining blood counts 3 times/wk for 6-8 wk. The requirement for repeated blood counts is necessary because some of the elastase mutations overlap with those in patients who have severe congenital neutropenia. Demonstrating oscillation or a lack thereof in the blood counts helps to identify the patients risk for progression to myelodysplastic syndrome (MDS)/acute myelogenous leukemia (AML), a risk that is only associated with severe congenital neutropenia. The diagnosis can be confirmed with genetic studies demonstrating a mutation in the ELANE gene. Affected patients with neutrophil nadirs <200/µL are treated with filgrastim and their cycle of profound neutropenia changes from a 21-day period with at least 3-5 days of profound neutropenia to a 9-11 day interval with 1 day of less-profound neutropenia. The dose needed to maintain nadirs >500/µL is usually 2-4 µg/kg/day administered daily or every other day.

**Severe congenital neutropenia (SCN) is a rare, genetically heterogeneous, congenital granulopoietic disorder with an estimated incidence of 1-2 cases per 1 million population. The disorder is characterized by an arrest in myeloid maturation at the promyelocyte stage in the bone marrow, resulting in ANCs consistently <200/µL and may occur sporadically, with autosomal dominant or recessive inheritance. The dominant form is caused most often by mutations in the ELANE gene, which accounts for 60-80% of SCN cases, while recessive forms arise from mutations in HAX1 (the form also known as Kostmann disease) or G6P3C (encoding a myeloid-specific isofrom of glucose-6-phosphatase). HAX1 mutations may be associated with neurologic deficits, and G6P3C with heart defects, urogenital abnormalities, and venous angiectasia. In addition to severe neutropenia, peripheral blood counts generally show monocytosis and many also exhibit eosinophilia; chronic inflammation may lead to secondary anemia and thrombocytosis. Patients who have SCN experience frequent episodes of fever, skin infections (including omphalitis), oral ulcers, gingivitis, pneumonia and perirectal abscesses, typically appearing in the 1st few mo of life. Infections often disseminate to the blood, meninges and peritoneum, and are usually caused by S. aureus, Escherichia coli, and Pseudomonas species. Prior to the current era of filgrastim therapy, most patients died of infectious complications within the 1st 1-2 yr of life despite prophylactic antibiotics.

More than 95% of SCN patients respond to filgrastim treatment with an increase in the ANC and a decrease in infections. Doses required to achieve an ANC >1000/µL vary greatly. A starting dose of filgrastim 5 µg/kg/day is recommended; the dose should be gradually increased, if necessary, as high as 100 µg/kg/day to attain an ANC of 1000-2000/µL. The 5% of patients who do not respond to filgrastim or who require high doses (>8 µg/kg/day) should be considered for hematopoietic stem cell transplantation. Besides infections, patients with SCN are at risk for developing MDS associated with monosomy 7 and AML. For this reason, regular monitoring with blood counts and yearly bone marrow surveillance, including karyotyping and fluorescence in situ hybridization, should be performed on all SCN patients. Although clonal cytogenetic abnormalities may spontaneously remit, their appearance should be considered a strong indication for hematopoietic stem cell transplantation, which is much more likely to be successful prior to progression to MDS/AML.

**Disorders of Molecular Processing.** Shwachman-Diamond syndrome (SDS) is an autosomal recessive disorder classically characterized by neutropenia, pancreatic insufficiency, and short stature with skeletal abnormalities. SDS is caused by proapo potic mutations of the SBDS gene, which encodes a protein that plays a role in ribosome biogenesis and RNA processing. The initial symptoms are usually steatorrhea and failure to thrive because of malabsorption, which usually develops by 4 mo of age, although the gastrointestinal symptoms may be subtle in some patients and go unrecognized. Patients have also been reported to have respiratory problems with frequent otitis media, pneumonia and eczema. Virtually all patients with SDS have neutropenia, with the ANC periodically <1000/µL. Some children have defects in chemotaxis or in the number or function of B, T, and natural killer (NK) cells that may contribute to the increased susceptibility to pyogenic infection. The diagnosis of SDS is based on clinical

phenotype; approximately 90% of patients have mutations identified in the SBDS gene. SDS may progress to bone marrow hypoplasia or to MDS/AML; cytogenetic abnormalities, particularly isochromosome i(7q) and del(20q), often precede conversion to MDS, so bone marrow monitoring is warranted. Treatment includes pancreatic enzyme replacement, plus filgrastim in patients with severe neutropenia.

**Dyskeratosis congenita,** a disorder of telomerase activity, most often presents as bone marrow failure rather than isolated neutropenia. The classical phenotype also includes nail dystrophy, leukoplakia, malformed teeth, and reticulated hyperpigmentation of the skin, although many patients, particularly young ones, do not exhibit these clinical features.

**Vesicular Trafficking Disorders.** This group of very rare primary immunodeficiency syndromes (see Table 131-6) derives from autosomal recessive defects in the biogenesis or trafficking of lysosomes and related endosomal organelles. As a result, the syndromes share phenotypic characteristics including defects in melanosomes contributing to partial albinism, abnormal platelet function, and immunologic defects involving not only neutrophil number, but also the function of neutrophils, B lymphocytes, NK cells, and cytotoxic T lymphocytes. The syndromes share a high risk of hemophagocytic lymphohistiocytosis (HLH) as a result of defects in T and NK cells.

**Chédiak-Higashi syndrome,** best known for the characteristic giant cytoplasmic granules in neutrophils, monocytes, and lymphocytes, is a disorder of subcellular vesicular dysfunction caused by mutations in the LYST gene, with resultant giant granules in all granule-bearing cells. Patients have increased susceptibility to infections, mild bleeding diathesis, progressive peripheral neuropathy, and predisposition to life-threatening HLH. The only curative treatment is hematopoietic stem cell transplantation.

**Griscelli syndrome type II** also features neutropenia, partial albinism, and a high risk of HLH, but peripheral blood granulocytes do not show giant granules. Patients often have hypogammaglobulinemia. The disorder is caused by mutations in RAB27a, which encodes a small guanosine triphosphatase that regulates granule secretory pathways. The only curative treatment is hematopoietic stem cell transplantation.

**Disorders of Metabolism.** Recurrent infections with neutropenia are a distinctive feature of glycogen storage disease (GSD)
Infectious diseases: AIDS, hepatitis, influenza, sepsis, tuberculosis, typhoid
Iatrogenic: Corticosteroids, cytotoxic chemotherapy, high-dose PUVA, immunosuppressive therapy, radiation, thoracic duct drainage
Systemic diseases: Hodgkin disease, lupus erythematosus, myasthenia gravis, protein-losing enteropathy, renal failure sarcoidosis
Other: Aplastic anemia, dietary deficiencies, thermal injury

Leukocytosis is an elevation in the total leukocyte or white blood cell (WBC) count that is 2 SD above the mean count for a particular age (see Chapter 727). To evaluate the patient with leukocytosis, it is critical to determine which class of WBC is elevated in conjunction with the duration and extent of the leukocytosis. For discussion of WBC elevation caused by immature leukocytes in acute and chronic leukemias, see Chapter 495.

A WBC count exceeding 50,000/μL is termed a leukemoid reaction because of the similarity to some features of leukemia. Leukemoid reactions are usually neutrophilic, and unlike true leukemia, show only small proportions of immature myeloid cells, consisting primarily of band forms, occasional metamyelocytes, and progressively rarer myelocytes, promyelocytes, and blasts. The process is most frequently associated with septicemia and severe bacterial infections, including shigellosis, salmonellosis, and meningococcemia.

A proportion of immature neutrophil cells >5%, termed a left shift, indicates rapid release of cells from the bone marrow, consisting primarily of band forms, which usually constitute 1-5% of circulating neutrophil cells, or metamyelocytes and myelocytes, which are not usually found in the peripheral circulation. Higher degrees of left shift with more immature neutrophil precursors are indicative of serious bacterial infections and may be a dire sign of depletion of the bone marrow reserve pool of neutrophils. Marked left shift may occasionally be encountered with trauma, burns, surgery, acute hemolysis, or hemorrhage.

**NEUTROPHILIA**

Neutrophilia is an increase in the total number of blood neutrophils that is 2 SD above the mean count for age (see Chapter 727). Elevated absolute neutrophil counts represent disturbances of the normal equilibrium involving bone marrow neutrophil production, movement out of the marrow compartments into the circulation, and neutrophil destruction. Neutrophilia may arise either alone or in combination with other acute stress. Drugs commonly associated with neutrophilia include epinephrine, corticosteroids, and recombinant growth factors such as recombinant human granulocyte colony-stimulating factor (G-CSF; filgrastim) and recombinant human granulocyte-macrophage colony-stimulating factor. Epinephrine causes release into the circulation of a sequestered pool of neutrophils that normally marginate along the vascular endothelium. Corticosteroids accelerate the release of neutrophils and bands from a large storage pool within the bone marrow and impair the migration of neutrophils from the circulation into tissues. Acute neutrophilia in response to inflammation and infections occurs because of release of neutrophils from the marrow storage pool. The postmitotic marrow neutrophil pools are approximately 10 times the size of the blood neutrophil pool, and about half of these cells are bands and segmented neutrophils. In neutrophil production disorders, such as those associated with malignancies and cancer chemotherapy, the size of this pool may be reduced and the capacity to develop neutrophilia remains impaired. Exposure of blood to foreign substances such as hemodialysis membrane activates the complement system and causes transient neutropenia followed by neutrophilia because of release of bone marrow neutrophils. G-CSF and granulocyte-macrophage colony-stimulating factor cause acute and chronic neutrophilia by mobilizing cells from the marrow reserves and by stimulating neutrophil production.

**Chronic Acquired Neutrophilia**

Chronic acquired neutrophilia is usually associated with continued stimulation of neutrophil production resulting from persistent inflammatory reactions or chronic infections (e.g., tuberculosis), vasculitis, postsplenectomy states, Hodgkin disease, chronic myelogenous leukemia, chronic blood loss, sickle cell disease, some chronic hemolytic anemias, and prolonged administration of corticosteroids (see Table 132-1). Chronic neutrophilia can arise after expansion of cell production secondary to stimulation of cell divisions within the mitotic precursor pool, which consists of promyelocytes and myelocytes. Subsequently, the size of the postmitotic pool increases. These changes lead to an increase in the marrow reserve pool, which can be readily mobilized for release of neutrophils into the circulation. The neutrophil production rate can increase greatly in response to exogenously administered hematopoietic growth factors, such as G-CSF, with a maximum response taking at least 1 wk to develop.

**Lifelong Neutrophilia**

Congenital or acquired asplenia is associated with lifelong neutrophilia. Uncommon genetic disorders that present with neutrophilia include leukocyte function disorders such as leukocyte adhesion deficiency and Rac2 mutation (see Chapter 124), and systemic disorders such as familial cold urticaria, periodic fever syndromes, and familial myeloproliferative disease (see Table 132-1). Two kindreds have been reported with autosomal dominant hereditary neutrophilia, with 1 caused by an activating mutation in the G-CSF receptor gene that leads to an increased proliferation of neutrophil precursors and a heightened risk of myelodysplastic syndrome.
Evaluation of persistent neutrophilia requires a careful history, physical examination, and laboratory studies to search for infectious, inflammatory, and neoplastic conditions. The leukocyte alkaline phosphatase score of circulating neutrophils can differentiate chronic myelogenous leukemia, in which the level is uniformly near zero, from reactive or secondary neutrophilia, which feature normal to elevated levels.

**MONOCYTOSIS**

The average absolute blood monocyte count varies with age, which must be considered in the assessment of monocytosis. Given the role of monocytes in antigen presentation and cytokine secretion and as effectors of ingestion of invading organisms, it is not surprising that many clinical disorders give rise to monocytosis (Table 132-2). Most commonly, monocytosis occurs in patients recovering from myelosuppressive chemotherapy and is a harbinger of the return of the neutrophil count to normal. Monocytosis is occasionally a sign of an acute bacterial, viral, protozoal, or rickettsial infection, and may also occur in some forms of chronic neutropenia and postsplenectomy states. Chronic inflammatory conditions can stimulate sustained monocytosis, as can preleukemia, chronic myelogenous leukemia, lymphomas, and occasionally Hodgkin disease.

**Lymphocytosis**

The most common cause of lymphocytosis is an acute viral illness, as part of the normal T-cell response to the infection. In infectious mononucleosis, the B cells are infected with the Epstein-Barr virus and the T cells react to the viral antigens present in the B cells, resulting in atypical lymphocytes with characteristic large, vacuolated morphology. Other viral infections classically associated with lymphocytosis are cytomegalovirus and viral hepatitis. Chronic bacterial infections such as tuberculosis and brucellosis may lead to a sustained lymphocytosis. Pertussis is accompanied by marked lymphocytosis in approximately 25% of infants infected before 6 mo of age. Thyrotoxicosis and Addison disease are endocrine disorders associated with lymphocytosis. Persistent or pronounced lymphocytosis suggests acute lymphocytic leukemia.

**Basophilia**

Basophilia is defined as an absolute basophil count >120 cells/µL. Basophilia is a nonspecific sign of a wide variety of disorders and is usually of limited diagnostic importance. Basophilia is most often present in hypersensitivity reactions and frequently accompanies the leukocytosis of chronic myeloid leukemia.

Bibliography

Complement (C) was originally defined as the nonspecific, heat-labile complementary principal required with specific antibody to lyse bacteria. The 1st 4 components were numbered in the order of their discovery and are termed the classical pathway. Unfortunately, the components fix to the immune complex in a different order, C1423. Beyond this confusing start, complement is a logical, exquisitely balanced, and highly influential system that is fundamental to the clinical expression of host defense and inflammation. In addition, it is evolutionarily ancient, and as it coevolved with other physiologic systems, it developed the capacity to perform functions beyond just host defense. Among these, it promotes phagocytic removal of dying body cells, molecular debris, and synapses during brain formation. But it can also cause harm and has been implicated in more than 30 illnesses.

The complement system, an essential component of innate immunity, is broadly conceptualized as the classical, lectin, and alternative pathways, which interact and depend on each other for their full activity; the membrane attack complex (C5b6789), formed from activity of any pathway; cell membrane receptors that bind complement components or fragments to mediate complement activity; and a large array of serum and membrane regulatory proteins (Table 133-1).

Complement is a system of interacting proteins. The biologic functions of the system depend on the interactions of individual components, which occur in sequential, cascade fashion. Activation of each component, except the 1st, depends on activation of the prior component or components in the sequence. Interaction occurs along 3 pathways (Fig. 133-2): the classical pathway, in the order antigen–antibody–C1qrs–C4–C2–C3; the lectin (carbohydrate-binding) pathway, in the order microbial carbohydrate–lectin (mannose-binding lectin [MBL])–MBL-associated serine protease–C4–C2–C3; and the alternative pathway, in the order activator–C3b–C5–C6–C7–C8–C9.

Antibody accelerates the rate of activation of the alternative pathway, but activation can occur on appropriate surfaces in the absence of antibody. The classical and the alternative pathways interact with each other through the ability of both to activate C3.

Activation of the early-acting components of complement (C1423) results in the generation of a series of active enzymes, C1, C4, C2, and C3, on the surface of the immune complex or underlying cell. These enzymes cleave and activate the next component in the sequence. In contrast, the interaction among C5b, C6, C7, C8, and C9 is nonenzymatic and depends on changes in molecular configuration.

**CLASSICAL AND LECTIN PATHWAYS**

The classical pathway sequence begins with fixation of C1, by way of C1q to the Fc, non–antigen-binding part of the antibody molecule after antigen–antibody interaction. The C1 tricomplex changes

After C1423, complement nomenclature is logical and consists of only a few rules. Fragments of components resulting from cleavage by other components acting as enzymes are assigned lowercase letters (a, b, c, d, e); with the exception of C2 fragments, the smaller piece that is released into surrounding fluids is assigned the lowercase letter a, and the major part of the molecule, bound to other components or to some part of the immune complex, is assigned letter b—for example, C3a and C3b. Components of the alternative pathway, B and D, have been assigned uppercase letters, as have the control proteins I and H, which downregulate both pathways. C3, and especially its major fragment C3b, is a component of both the classical and alternative pathways.

Complement is a system of interacting proteins. The biologic functions of the system depend on the interactions of individual components, which occur in sequential, cascade fashion. Activation of each component, except the 1st, depends on activation of the prior component or components in the sequence. Interaction occurs along 3 pathways (Fig. 133-2): the classical pathway, in the order antigen–antibody–C1qrs–C4–C2–C3; the lectin (carbohydrate-binding) pathway, in the order microbial carbohydrate–lectin (mannose-binding lectin [MBL])–MBL-associated serine protease–C4–C2–C3; and the alternative pathway, in the order activator–C3b–C5–C6–C7–C8–C9.

Antibody accelerates the rate of activation of the alternative pathway, but activation can occur on appropriate surfaces in the absence of antibody. The classical and the alternative pathways interact with each other through the ability of both to activate C3.

Activation of the early-acting components of complement (C1423) results in the generation of a series of active enzymes, C1, C4, C2, and C3, on the surface of the immune complex or underlying cell. These enzymes cleave and activate the next component in the sequence. In contrast, the interaction among C5b, C6, C7, C8, and C9 is nonenzymatic and depends on changes in molecular configuration.

**CLASSICAL AND LECTIN PATHWAYS**

The classical pathway sequence begins with fixation of C1, by way of C1q to the Fc, non–antigen-binding part of the antibody molecule after antigen–antibody interaction. The C1 tricomplex changes
configuration and the C1s subcomponent becomes an active enzyme, “C1 esterase.” Certain bacteria, Mycoplasma, RNA viruses, and the lipid A component of bacterial endotoxin can activate C1q directly and trigger the full complement cascade.

As part of the innate immune response, broadly reactive “natural” antibodies and C-reactive protein, which reacts with carbohydrate from microorganisms and with dying cells, can substitute for specific antibody in the fixation of C1q and initiate reaction of the entire sequence. Endogenous agents, including uric acid crystals, amyloid deposits, DNA, and components of damaged cells such as apoprotic blebs and mitochondrial membranes, can activate C1q directly. But in this case, the ligand–C1q complex interacts strongly with the inhibitors C4-binding protein and factor H, allowing some C3-mediated opsonization and phagocytosis, but limiting the full inflammatory response typically triggered by microbes. C1q synthesized in the brain and retina enables the complement-dependent pruning of synapses that is essential for normal neural system development.

There are 4 recognition molecules in the lectin pathway: MBL and ficolins 1, 2, and 3. MBL is the prototype of the collectin family of carbohydrate-binding proteins (lectins) that are believed to play an important part in innate, nonspecific immunity; its structure is homologous to that of C1q. These lectins, in association with MBL-associated serine proteases 1, 2, and 3 (MASPs 1/2/3), can bind to mannose, lipoteichoic acid, and other carbohydrates on the surface of bacteria, fungi, parasites, and viruses. MASPs then function there like C1s to cleave C4 and C2 and activate the complement cascade. The peptide C4a has weak “anaphylatoxin” activity and reacts with mast cells to release the chemical mediators of immediate hypersensitivity, including histamine. C3a and C5a, released later in the sequence, are potent anaphylatoxins, and C5a is also an important chemotactic factor. Fixation of C4b to the complex permits it to adhere to neutrophils, macrophages, B cells, dendritic cells, and erythrocytes. MASP-2 can activate clotting by generating thrombin from prothrombin, which could prevent microbial spread.

Cleavage of C3 and generation of C3b is the next step in the sequence. The serum concentration of C3 is the highest of any component, and its activation is the most crucial step in terms of biologic activity. Cleavage of C3 can be achieved through the C3 convertase of the classical pathway, C142, or of the alternative pathway, C3bBb. Once C3b is fixed to a complex or dead or dying host cell, it can bind to cells with receptors for C3b (complement receptor 1 [CR1]), including B lymphocytes, erythrocytes, and phagocytic cells (neutrophils, monocytes, and macrophages). Efficient phagocytosis of most microorganisms in vitro, especially by neutrophils, requires binding of C3 to the microbe. The severe pyogenic infections that commonly occur in C3-deficient patients indicate that phagocytosis in vivo is also inefficient without C3. The biologic activity of C3b is controlled by cleavage by factor I to iC3b, which promotes phagocytosis on binding to the iC3b receptor (CR3) on phagocytes. Further degradation of iC3b by factor I and proteases yields C3dg, then C3d; C3d binds to CR2 on B lymphocytes and thereby serves as a costimulator of antigen-induced B-cell activation.

**ALTERNATIVE PATHWAY**

The alternative pathway can be activated by C3b generated through classical pathway activity or proteases from neutrophils or the clotting system. It can also be activated by a form of C3 created by low-grade, spontaneous reaction of native C3 with a molecule of water, a “tick-over” that occurs constantly in plasma. Once formed, C3b or the hydrolyzed C3 can bind to any nearby cell or to factor B. Factor B attached to C3b in the plasma or on a surface can be cleaved to Bb by the protease factor D. The complex C3bBb becomes an efficient C3 convertase, which generates more C3b through an amplification loop. Properdin can bind to C3bBb, increasing stability of the enzyme and protecting it from inactivation by factors I and H, which modulate the loop and the pathway.

Certain “activating surfaces” promote alternative pathway activation if C3b is fixed to them, including bacterial teichoic acid or endotoxin, virally infected cells, antigen–immunoglobulin A complexes, and cardiopulmonary bypass and renal dialysis membranes. These surfaces act by protecting the C3bBb enzyme from the control otherwise exercised by factors I and H. Rabbit red blood cell membrane is such a surface, which serves as the basis for an assay of serum alternative pathway activity. Sialic acid on the surface of microorganisms or cells prevents formation of an effective alternative pathway C3 convertase by promoting activity of factors I and H. Nevertheless, significant activation of C3 can occur through the alternative pathway, and the resultant biologic activities are qualitatively the same as those achieved through activation by C142 (see Fig. 133-2).

**MEMBRANE ATTACK COMPLEX**

The sequence leading to cytokinesis begins with the association of C5b to the C5-activating enzyme from the classical pathway, C4b2a3b, and from the alternative pathway, C3bBb3b. C6 is bound to C5b without being cleaved, stabilizing the activated C5b fragment. The C5b6 complex then dissociates from C423 and reacts with C7. C5b67 complexes must attach promptly to the membrane of the parent or a bystander cell, or they lose their activity. Next, C8 binds, and the C5b678 complex then promotes the addition of multiple C9 molecules. The C9 polymer of at least 3-6 molecules forms a transmembrane channel, and lysis ensues.

**CONTROL MECHANISMS**

Without control mechanisms acting at multiple points, there would be no effective complement system, and unbridled consumption of components would generate severe, potentially lethal damage to the host. At the 1st step, C1 inhibitor (C1 INH) inhibits C1r and C1s enzymatic activity and, thus, the cleavage of C4 and C2. C1 INH also inhibits MASPs-2, factors Xa and XIIa of the clotting system, and kallikrein of the contact system. Activated C2 has a short half-life, and this relative instability limits the effective life of C42 and C423. The alternative pathway enzyme that activates C3, C3bBb, also has a short half-life, though it can be prolonged by the binding of properdin (P) to the enzyme complex. P can also bind directly to microbes and promote assembly of the alternative pathway C3 convertase.

Serum contains the enzyme carboxypeptidase N, which cleaves the N-terminus arginine from C4a, C3a, and C5a, thereby limiting their biologic activity. Factor I inactivates C4b and C3b; factor H accelerates inactivation of C3b by factor I; and an analogous factor, C4-binding protein (C4-bp), accelerates C4b cleavage by factor I, thus limiting assembly of the C3 convertase. Three protein constituents of cell membranes, CR1, membrane cofactor protein (MCP), and decay-accelerating factor (DAF), promote the disruption of C3 and C5 convertases assembled on those membranes. Another cell membrane-associated protein, CD59, can bind C8 or both C8 and C9 and thereby interfere with insertion of the membrane attack complex (C5b6789). The serum proteins vitronectin and clusterin can inhibit attachment of the C5b67 complex to cell membranes. Both C8 or C9 in a full membrane attack complex, or otherwise interfere with the formation or insertion of this complex. Vitronectin also promotes macrophage uptake of dying neutrophils. The genes for the regulatory proteins factor H, C4-bp, MCP, DAF, CR1, and CR2 are clustered on chromosome 1.

**PARTICIPATION IN HOST DEFENSE**

Neutralization of virus by antibody can be enhanced with C1 and C4 and further enhanced by the additional fixation of C3b through the classical or alternative pathway. Complement may, therefore, be particularly important in the early phases of a viral infection when antibody is limited. Antibody and the full complement sequence can also eliminate infectivity of at least some viruses by the production of typical complement “holes,” as seen by electron microscopy. Fixation of C1q can opsonize (promote phagocytosis) through binding to the C1q receptor.

C4a, C3a, and C5a can bind to mast cells and thereby trigger release of histamine and other mediators, leading to vasodilation and the swelling and redness of inflammation. C5a can enhance macrophage phagocytosis of C3b-opsonized particles and induce macrophages to release the cytokines tumor necrosis factor and interleukin 1. C5a is a major chemotactic factor for neutrophils, monocytes, and eosinophils, which can efficiently phagocytize microorganisms opsonized with C3b.
or cleaved C3b (iC3b). Further inactivation of cell-bound C3b by cleavage to C3d and C3dg removes its opsonizing activity, but it can still bind to B cells. Fixation of C3b to a target cell can enhance its lysis by natural killer cells or macrophages.

Insoluble immune complexes can be solubilized if they bind C3b, apparently because C3b disrupts the orderly antigen-antibody lattice. Binding C3b to a complex also allows it to adhere to C3 receptors (CR1) on red blood cells, which then transport the complexes to hepatic and splenic macrophages for removal. This phenomenon may at least partially explain the immune complex disease found in patients who lack C1, C4, C2, or C3.

The complement system serves to link the innate and adaptive immune systems. C4b or C3b coupled to immune complexes promotes their binding to antigen-presenting macrophages, dendritic cells, and B cells. Coupling of antigen to C3d allows binding to CR2 on B cells, which markedly reduces the amount of antigen needed to trigger an antibody response.

Neutralization of endotoxin in vitro and protection from its lethal effects in experimental animals require C1 INH and later-acting components of complement, at least through C6. Finally, activation of the entire complement sequence can result in lysis of virus-infected cells, tumor cells, and most types of microorganisms. Bactericidal activity of complement has not appeared to be important to host defense, except for the occurrence of Neisseria infections in patients lacking later-acting components of complement (see Chapter 134).

134.1 Evaluation of the Complement System

Richard B. Johnston Jr.

Testing for total hemolytic complement activity (CH$_{50}$) effectively screens for most of the common diseases of the complement system. A normal result in this assay depends on the ability of all 11 components of the classical pathway and membrane attack complex to interact and lyse antibody-coated sheep erythrocytes. The dilution of serum that lyses 50% of the cells determines the end point. In congenital deficiencies of C1 through C8, the CH$_{50}$ value is 0 or close to 0; in C9 deficiency, the value is approximately half-normal. Values in the acquired deficiencies vary with the type and severity of the underlying disorder. This assay does not detect deficiency of mannose-binding lectin (MBL), factors D or B of the alternative pathway, or properdin (Fig. 134-1). Deficiency of factors I or H permits consumption of C3, with partial reduction in the CH$_{50}$ value. When clotted blood or serum sits at room temperature or warms, CH$_{50}$ activity begins to decline, which leads to values that are falsely low but not zero. It is important to separate the serum and freeze it at $-70^\circ$C ($-94^\circ$F) by no more than 1 hr after blood draw.

In hereditary angioedema, depression of C4 and C2 during an attack significantly reduces the CH$_{50}$. Typically, C4 is low and C3 normal or slightly decreased. Concentrations of C1 inhibitor protein will be normal in 15% of cases; but C1 acts as an esterase, and the diagnosis can be established by showing increased capacity of patients’ sera to hydrolyze synthetic esters.

A decrease in serum concentration of both C4 and C3 suggests activation of the classical pathway by immune complexes. Decreased C3 and normal C4 levels suggest activation of the alternative pathway. This difference is particularly useful in distinguishing nephritis secondary to immune complex deposition from that caused by NeF (nephritic factor). In the latter condition and in deficiency of factor I or H, factor B is consumed and C3 serum concentration is low. Alternative pathway activity can be measured with a relatively simple and reproducible hemolytic assay that depends on the capacity of rabbit erythrocytes to serve as both an activating (permissive) surface and a target of alternative pathway activity. This assay (AP$_{50}$) detects deficiency of properdin, factor D, and factor B. Immunochemical methods can be used to quantify individual components of all 3 pathways, guided by results of the screening hemolytic assays. It is possible to analyze the genes encoding most of the components.

A defect of complement function should be considered in any patient with recurrent angioedema, autoimmune disease (especially systemic lupus erythematosus [SLE]), chronic nephritis, hemolytic-uremic syndrome, or partial lipodystrophy, or with recurrent pyogenic infections, disseminated meningococcal or gonococcal infection, or a second episode of bacteremia at any age. A previously well adolescent or young adult with meningococcal meningitis caused by an uncommon serotype (not A, B, or C) should undergo screening for a late-component or alternative pathway deficiency with CH$_{50}$ and AP$_{50}$ assays.

*B9 deficiency may have up to 30% normal CH$_{50}$ with low AP$_{50}$

**Figure 134-1** Flow chart for the evaluation of inherited complement deficiencies using hemolytic screening assays for the classical (CH$_{50}$) and alternative pathways (AP$_{50}$). For each assay, the entire activation pathway including the membrane attack complex (MAC) is required for lysis. (Modified from Rich RR, Fleisher TA, Shearer WT, et al, editors, Clinical immunology: principles and practice, ed 4, Philadelphia, 2012, WB Saunders, Fig. 20-8, p. 262.)

134.2 Genetic Deficiencies of Complement Components

Richard B. Johnston Jr.

Congenital deficiencies of all 11 components of the classical-membrane attack pathway and of factor D and properdin of the alternative pathway are described in Table 134-1. All of the components of the

* A finding was reported as "very common" if it occurred in 50% or more of reported cases, "common" if reported in approximately 5-50% of cases, and "occasional" if present in 1 or 2 cases or <5% of the more frequent deficiencies.

Classical and alternative pathways except properdin are inherited as autosomal recessive codominant traits. Each parent transmits a gene that codes for synthesis of half the serum level of the component. Deficiency results from inheritance of 1 null gene from each parent; the hemizygous parents typically have low normal CH50 levels and no consequences of the partial deficiency. Properdin deficiency is transmitted as an X-linked trait.

Most patients with primary C1q deficiency have SLE; some have an SLE-like syndrome without typical SLE serology, a chronic rash with underlying vasculitis, or membranoproliferative glomerulonephritis (MPGN). Some C1q-deficient children have serious infections, including septicemia and meningitis. Individuals with C1r, C1s, combined C1r/C1s, C4, C2, or C3 deficiency also have a high incidence of autoimmune syndromes (see Table 134-1), especially SLE or an SLE-like syndrome without an elevated antinuclear antibody level.

C4 is encoded by 2 genes, C4A and C4B. C4 deficiency represents absence of both gene products. Complete deficiency of only C4A, present in approximately 1% of the population, also predisposes to SLE, although C4 levels are only partially reduced. Patients with only C4B deficiency may be predisposed to infection. A few patients with C5, C6, C7, or C8 deficiency have SLE, but recurrent meningococcal infections are much more likely to be the major problem.

There are at least 2 possible reasons for the concurrence of complement component deficiencies, especially C1, C4, C2, or C3 deficiency, and autoimmune–immune complex diseases. First, deposition of C3 on autoimmune complexes facilitates their removal from the circulation through binding to complement receptor 1 (CR1) on erythrocytes and transport to the spleen and liver. Second, the early components, particularly C1q and C3, expedite the clearance of necrotic and apoptotic cells, which are sources of autoantigens.
Individuals with C2 deficiency carry the risk of life-threatening septicemic illnesses, most commonly caused by pneumococci. However, most have not had problems with increased susceptibility to infection, presumably because of the protective function of the alternative pathway. The genes for C2, factor B, and C4 are situated close to each other on chromosome 6, and a partial depression of factor B levels can occur in conjunction with C2 deficiency. Persons with a deficiency of both proteins may be at particular risk.

Because C3 can be activated by C142 or by the alternative pathway, a defect in the function of either pathway can be compensated for, at least to some extent. Without C3, however, opsonization of bacteria is inefficient, and the chemotactic fragment from C5 (C5a) is not generated. Some organisms must be well opsonized in order to be cleared, and genetic C3 deficiency has been associated with recurrent, severe pyogenic infections caused by pneumococci, Haemophilus influenzae, and meningococci.

More than half of the individuals reported to have congenital C5, C6, C7, or C8 deficiency have had meningococcal meningitis or extra-genital gonococcal infection. Patients with C9 deficiency, which is most often reported in individuals of Japanese descent, retain about one-third normal CH50 titers; some of these patients have also had Neisseria disease. In studies of patients 10 yr of age and older with systemic meningococcal disease, 3-15% have had a genetic deficiency of C5, C6, C7, C8, C9, or properdin. Among patients with infections caused by the uncommon Neisseria meningitidis serogroups (X, Y, Z, W135, 29E, or nongroupable; not A, B, or C), 33-45% have an underlying complement deficiency. It is not clear why patients with a deficiency of 1 of the late-acting components suffer a particular predisposition to Neisseria infections. It may be that serum bacteriolysis is uniquely important in defense against this organism. Many persons with such a deficiency have no significant illness.

A few individuals have been identified with deficiency of factor D of the alternative pathway, all with recurrent infections, most often neisserial. Hemolytic complement activity and C3 levels in their serum were normal, but alternative pathway activity was markedly deficient or absent.

Mutations in the structural gene encoding MBL or polymorphisms in the promoter region of the gene result in pronounced interindividual variation in the level of circulating MBL. More than 90% of individuals with MBL deficiency do not express a predisposition to infection. Those with a very low level of MBL have a predisposition to recurrent respiratory infections in infancy and to serious pyogenic and fungal infections if there is another underlying defect of host defense. MBL-associated serine protease (MASP)-2 deficiency has been reported with SLE-like symptoms and recurrent pneumococcal pneumonia. Homozygous ficolin-3 deficiency is associated with repeated pneumonia since early childhood, cerebral abscesses, and bronchiectasis.

Bibliography is available at Expert Consult.

134.3 Deficiencies of Plasma, Membrane, or Serosal Complement Control Proteins
Richard B. Johnston Jr.

Congenital deficiencies of 5 plasma complement control proteins have been described (see Table 134-1). Factor I deficiency was reported originally as a deficiency of C3 resulting from hypercatabolism. The first patient described had suffered a series of severe pyogenic infections similar to those associated with agammaglobulinemia or congenital deficiency of C3. Factor I is an essential regulator of both pathways. Its deficiency permits prolonged existence of C3b as a part of the C3 convertase of the alternative pathway, C3bBb. This results in constant activation of the alternative pathway and cleavage of more C3 to C3b, in circular fashion. Intravenous infusion of plasma or purified factor I induced a prompt rise in serum C3 concentration in the patient and a return to normal of in vitro C3-dependent functions such as opsonization.

The effects of factor H deficiency are like those of factor I deficiency because factor H also assists in dismantling the alternative pathway C3 convertase. A trigger event such as infection initiates uninhibited continuous activation of the alternative pathway, which consumes C3, factor B, total hemolytic activity, and alternative pathway activity. Patients have sustained systemic infections due to pyogenic bacteria, particularly N. meningitidis. Many have had glomerulonephritis or atypical hemolytic uremic syndrome (aHUS) (see Chapter 518). Mutations in genes encoding membrane cofactor protein (MCP; CD46), factors I or B, or C3, or the endothelial antiinflammatory protein thrombomodulin, or autoantibodies to factors H or B, also are associated with aHUS. The majority of patients with factor H deficiency and aHUS, typically younger than 2 yr of age, develop end-stage renal disease or die. The few patients thus far reported as having C4-binding protein deficiency have approximately 25% of the normal levels of the protein and no typical disease presentation, although 1 had angioedema and Behçet disease.

Persons with properdin deficiency have a striking predisposition to N. meningitidis meningitis. All reported patients have been male. The predisposition to infection in these patients demonstrates clearly the need for the alternative pathway in defense against bacterial infection. Serum hemolytic complement activity is normal in these patients, and if the patient has specific antibacterial antibody from immunization or prior exposure, the need for the alternative pathway and properdin is greatly reduced. Several patients have had dermal vasculitis or discoid lupus.

Hereditary angioedema occurs in persons unable to synthesize normal levels of active C1 inhibitor (C1 INH). In 85% of affected families, the patient has markedly reduced concentrations of inhibitor, averaging 30% of normal; the other 15% have normal or elevated concentrations of an immunologically cross-reacting but nonfunctional protein. Both forms of the disease are transmitted as autosomal dominant traits. C1 INH suppresses the complement proteases C1r and MASP-2 and the activated proteases of the contact and fibrinolysis systems. In doing so, C1 INH is consumed as a “suicide inhibitor.” In the absence of full C1 INH function, activation of any of these proteases tips the balance toward the protease. This activation leads to uncontrolled C1 and kallikrein activity with breakdown of C4 and C2 and release of bradykinin, which interacts with vascular endothelial cells to cause vasodilation, which produces localized, nonpitting edema. The biochemical triggers that induce attacks of angioedema in these patients are not well understood.

Swelling of the affected part progresses rapidly, without urticaria, itching, discoloration, or redness and often without severe pain. Swelling of the intestinal wall, however, can lead to intense abdominal cramping, sometimes with vomiting or diarrhea. Concomitant subcutaneous edema is often absent, and patients have undergone abdominal surgery or psychiatric examination before the true diagnosis was established. Laryngeal edema can be fatal. Attacks last 2-3 days and then gradually abate. They may occur at sites of trauma, especially dental, after vigorous exercise, or with menses, fever, or emotional stress. Attacks begin in the 1st 5 yr of life in almost half of patients, but are usually not severe until late childhood or adolescence. Acquired C1 INH deficiency can occur in association with B-cell cancer or autoantibody to C1 INH. SLE and glomerulonephritis have been reported in patients with the congenital disease.

Three of the membrane complement control proteins—CR1, MCP (CD46), and decay-accelerating factor (DAF)—prevent the formation of the full C3-cleaving enzyme, C3bBb, which is triggered by C3b deposition. CD59 (membrane inhibitor of reactive lysis) prevents the full development of the membrane attack complex that creates the “hole.” Paroxysmal nocturnal hemoglobinuria (PNH) is a hemolytic anemia that occurs when DAF and CD59 are not expressed on the erythrocyte surface. The condition is acquired as a somatic mutation in a hematopoietic stem cell of the PIG-A gene on the X chromosome. The product of this gene is required for normal synthesis of a
Bibliography
glycosyl-phosphatidylinositol molecule that anchors about 20 proteins to cell membranes, including DAF and CD59. One patient with genetic isolated CD59 deficiency had a mild PNH-like disease in spite of normal expression of membrane DAF. In contrast, genetic isolated DAF deficiency has not resulted in hemolytic anemia.

Bibliography is available at Expert Consult.

134.4 Secondary Disorders of Complement

Richard B. Johnston Jr.

Partial deficiency of C1q has occurred in patients with severe combined immunodeficiency disease or hypogammaglobulinemia, apparently secondary to the deficiency of immunoglobulin (Ig) G, which normally binds reversibly to C1q and prevents its rapid catabolism.

Chronic MPGN can be caused by NeF, an IgG autoantibody to the C3—cleaving enzyme of the alternative pathway, C3bbB, which protects the enzyme from inactivation and promotes over activation of the alternative pathway. The result is increased consumption of C3 and decreased concentration of serum C3. Pyogenic infections, including meningitis, may occur if the serum C3 level drops to <10% of normal. This disorder has been found in children and adults with partial lipodystrophy. Adipocytes are the main source of factor D and synthesize C3 and factor B; exposure to NeF induces their lysis. An IgG NeF that binds to and inhibits the breakdown of C4d, the classical pathway C3 convertase, has been described in acute postinfectious nephritis and in SLE. The consumption of C3 that characterizes poststreptococcal nephritis and SLE could be caused by this factor, by complement activation by immune complexes, or by both.

Newborn infants have mild to moderate reductions in all plasma components of the complement system. Opsonization and generation of chemotactic activity in serum from full-term newborns can be markedly deficient through either the classical or alternative pathway. Complement activity is even lower in preterm infants. Patients with severe chronic cirrhosis of the liver, hepatic failure, malnutrition, or anorexia nervosa can have significant deficiency of complement components and functional activity. Synthesis of components is depressed in these conditions, and serum from some patients with malnutrition also contains immune complexes that could accelerate depletion.

Patients with sickle cell disease have normal activity of the classical pathway, but some have defective function of the alternative pathway in opsonization of pneumococci, in bacteriolysis and opsonization of Salmonella, and in lysis of rabbit erythrocytes. Deoxygenation of erythrocytes from patients with sickle cell disease alters their membranes to increase exposure of phospholipids that can activate the alternative pathway and consume its components. This activation is accentuated during painful crisis. Children with nephrotic syndrome may have decreased serum levels of factors B and D and subnormal serum opsonization activity.

Immune complexes initiated by microorganisms or their by-products can induce complement consumption. Activation occurs primarily through fixation of C1 and initiation of the classical pathway. Formation of immune complexes and consumption of complement have been demonstrated in lepromatous leprosy, bacterial endocarditis, infected ventriculoperiocular shunts, malaria, infectious mononucleosis, dengue hemorrhagic fever, and acute hepatitis B. Nephritides or arthritis can develop as a result of deposition of immune complexes and activation of complement in these infections. In SLE, immune complexes activate C1q, and C3 is deposited at sites of tissue damage, including kidneys and skin; depressed synthesis of C3 is also noted. The syndrome of recurrent urticaria, angioedema, eosinophilia, and hypocomplementemia secondary to activation of the classical pathway may be due to autoantibody to C1q and circulating immune complexes. Circulating immune complexes and decreased C3 have been reported in some patients with dermatitis herpetiformis, celiac disease, primary biliary cirrhosis, and Raye syndrome.

Circulating bacterial products in sepsis or tissue factors released after severe trauma can initiate activation of the classical and alternative pathways, leading to increased serum levels of C3a, C5a, and C5b-9 and systemic inflammatory response syndrome and multiple organ failure. C5a and its receptors, particularly on neutrophils, appear to be central to the pathogenesis of systemic inflammatory response syndrome. Intravenous injection of iodinated roentgenographic contrast medium can trigger a rapid and significant activation of the alternative pathway, which may explain the occasional reactions that occur in patients undergoing this procedure.

Burns can induce massive activation of the complement system, especially the alternative pathway, within a few hours after injury. Resulting generation of C3a and C5a stimulates neutrophils and induces their sequestration in the lungs, leading to shock lung. Cardiopulmonary bypass, extracorporeal membrane oxygenation, plasma exchange, or hemodialysis using cellophane membranes may be associated with a similar syndrome as a result of activation of plasma complement, with release of C3a and C3b. In patients with erythropoietic protoporphyria or porphyria cutanea tarda, exposure of the skin to light of certain wavelengths activates complement, generating chemotactic activity. This chemotactic activity leads to lysis of capillary endothelial cells, mast cell degranulation, and the appearance of neutrophils in the dermis.

Some tumor cells can avoid complement-mediated lysis by overexpressing DAF, MCP, CD59, CR1, or factor H, or by secreting proteases that cleave tumor-bound C3b. Microorganisms have evolved similar evasive mechanisms; for example, HIV-1 particles budding from infected cells acquire the membrane proteins DAF and CD59, and staphylococci can produce multiple complement inhibitors.

Bibliography is available at Expert Consult.

134.5 Treatment of Complement Disorders

Richard B. Johnston Jr.

No specific therapy is available at present for genetic deficiencies of the components of the classical, alternative, and lectin complement pathways. Much can be done, however, to protect patients with any of these disorders from serious complications; and specific treatment is available for 3 disorders caused by control-protein deficiencies, hereditary angioedema, aHUS, and PNH.

Management of hereditary angioedema starts with avoidance of precipitating factors, usually trauma. Infusion of C1 INH concentrate (nanofiltered C1-esterase inhibitor), an inhibitor of kallikrein (elastase) that blocks bradykinin production, and an antagonist of the bradykinin receptor (icatibant) are approved in the United States for use in adolescents and adults for long-term prophylaxis, preparation for surgery or dental procedures, or treatment of acute attacks. The synthetic androgen oxandrolone increases the level of functional C1 INH severalfold and is approved for cautious use in children. Antihistamines, adrenal, and corticosteroids have no effect. Eculizumab, a humanized monoclonal antibody to C5, is an effective treatment for PNH and aHUS.

Effective supportive management is available for other primary diseases of the complement system, and identification of a specific defect in the complement system can have an important impact on management. Concern for the associated complications such as autoimmune disease and infection should encourage vigorous diagnostic efforts and earlier institution of therapy. Individuals with SLE and a complement defect generally respond as well to therapy as do those without complement deficiency. With the onset of unexplained fever, cultures should be obtained and antibiotic therapy instituted more quickly and with less stringent indications than in a normal child. The parent or patient should be given letters describing any predisposition to systemic bacterial infection or autoimmune disease associated with the patient’s deficiency, along with the recommended approach to management, for possible use by school, camp, or emergency room physicians. The

patient and close household contacts should be immunized against *H. influenzae*, *Streptococcus pneumoniae*, and *N. meningitidis*. High titers of specific antibody might opsonize effectively without the full complement system, and immunization of household members could reduce the risk of exposing patients to these particularly threatening pathogens. Repeat immunization of patients is advisable since complement deficiency can be associated with a blunted or shorter-lived antibody response than normal.

Considering the many conditions in which complement is a central mediator of disease, there is an intensive effort to develop therapeutic complement inhibitors. These include soluble CR1 and inhibitors of C5 convertase and C3a and C5a binding. Heparin, which inhibits both classical and alternative pathways, has been used to prevent "post-pump syndrome."

Cell Transplantation

Chapter 135
Principles and Clinical
Indications of
Hematopoietic Stem
Cell Transplantation
Andrea Velardi and Franco Locatelli

Thousands of children have received an infusion of either allogeneic 
(from a donor) or autologous (from the same individual) hematopoietic 
stem cells to cure both malignant and nonmalignant disorders. 
Autologous transplantation is employed as a rescue strategy after 
delivering otherwise lethal doses of radiotherapy and chemotherapy in 
children with hematologic malignancies such as relapsed lymphoma or selected solid tumors (e.g., neuroblastoma, brain tumors). Allogeneic 
transplantation is used to treat children with genetic diseases of 
blood cells, such as thalassemia and primary immunodeficiency dis-
eases, as well as hematologic malignancies, such as leukemia and 
myelodysplastic syndromes. Since 1968 and for many years, bone 
marrow has represented the only source of hematopoietic progenitors 
employed. Growth factor (granulocyte colony-stimulating factor)–
mobilized peripheral blood hematopoietic stem cells and umbilical 
cord blood hematopoietic progenitors have been more recently intro-
duced in the clinical practice to perform hematopoietic stem cell trans-
plantation (HSCT).

An human leukocyte antigen (HLA)–matched sibling was once the 
only type of donor employed. Today, matched unrelated volunteers, 
full-haplotype mismatched family members, and unrelated cord blood 
donors have been largely employed to transplant patients lacking an 
HLA-identical relative.

Protocols for allogeneic HSCT consist of 2 parts: the preparative 
regimen and transplantation itself. During the preparative condition-
ing regimen, chemotherapy, often associated with irradiation, is 
administered to destroy the patient’s hematopoietic system and to sup-
press the immune system, especially T cells, so that graft rejection is 
prevented. In patients with malignancies, the preparative regimen also 
serves to significantly reduce the tumor burden. The patient then 
receives an intravenous infusion of hematopoietic cells from the donor. 
Less-aggressive conditioning regimens, known as reduced intensity 
conditioning regimens, are also used in pediatric patients. These 
regimens are mainly immune-suppressive and aim at inducing a state of 
reduced immune competence of the recipient permitting to avoid the 
rejection of donor cells.

The immunology of HSCT is distinct from that of other types of 
transplant because, in addition to stem cells, the graft contains mature 
blood cells of donor origin, including T cells, B cells, natural killer cells, 
and dendritic cells. These cells repopulate the recipient’s lymphohema-

toietic system and give rise to a new immune system, which helps 
eliminate residual leukemia cells that survive the conditioning regimen. 
This effect is known as the graft-versus-leukemia (GVL) effect.

The donor immune system exerts its T-cell–mediated GVL effect 
through alloreactions directed against not shared recipient histocom-
patibility antigens displayed on recipient leukemia cells. Because some of 
these histocompatibility antigens are also displayed on tissues, 
however, T-cell–mediated alloreactions may ensue. Specifically, donor 
alloreactive cytotoxic CD8+ effector T cells may attack recipient 
tissues—in particular, the skin, gastrointestinal tract, and liver— 
causing acute graft-versus-host disease (GVHD), a condition of 
varying severity, that, in some cases, can be life-threatening or even 
fatal (see Chapter 137). Although the main benefit for allogeneic HSCT 
recipients with leukemia derives from the GVL effect displayed by 
immune-competent cells, disease recurrence remains the main cause 
of treatment failure. The risk of failing to eradicate leukemia is influ-
enced by many variables, including disease phase, molecular lesions of 
tumor cells, and disparity for major or minor histocompatibility anti-
gens in the donorrecipient pairs. Strategies for rescuing patients expe-
riencing disease recurrence are mainly based on either second 
transplantation or infusion of donor leukocytes. To overcome the 
hurdle of tumor elusion caused by HLA-loss on malignant cells, the 
use of non-HLA–restricted chimeric antigen receptors (CARs) has 
been envisaged. This therapeutic strategy is based on genetic repro-
gramming of T cells through artificial immune receptors that repro-
ducibly and efficiently redirect the antigen specificity of polyclonal T 
lymphocytes toward target antigens expressed by leukemic cells. When 
expressed by T cells, CARs mediate antigen recognition and tumor 
cytolysis in an major histocompatibility complex (MHC)–unrestricted 
fashion, and can target any molecule (protein, carbohydrate, or glyco-
lipid) expressed on the surface of tumor cells, thus bypassing one of 
the major tumor escape mechanisms based on the down regulation of 
MHC molecules. CARs are composed of an extracellular specific 
antigen-binding moiety, obtained from the variable regions of a mono-
clonal antibody, linked together to form a single-chain antibody (scFv), 
and of an intracellular signaling component derived from the ζ chain of 
the T-cell–receptor–CD3 complex. The addition to the CAR gene 
construct of costimulation signals and cytokines promoting T-cell 
expansion and/or survival improves the antitumor efficiency of the 
engineered T cells and their survival in the tumor milieu. Gamma 
retrovirus and lentiviruses are usually used to transduce CARs into T 
lymphocytes to be employed in the clinical setting. These vectors have 
been shown to efficiently infect T lymphocytes, integrate into the host 
genome and produce robust expression of the gene in human T cells 
and their progeny.

The success of allogeneic HSCT is undermined by diversity between 
donors and recipients in major and minor histocompatibility antigens. 
MHC molecules, the HLA-A, HLA-B, and HLA-C MHC class I mol-
eecules, present peptides to CD8+ T cells, while the HLA-DR, HLA-DQ, 
and HLA-DP MHC class II molecules present peptides to CD4+ T 
cells. There are hundreds of variant forms of each class I and class II 
molecule, and even small differences can elicit alloreactive T-cell
hematopoietic stem cell transplantation from an HLA-identical sibling. Because polymorphic HLA genes are closely linked and usually constitute a single genetic locus, any pair of siblings has a 25% chance of being HLA identical. Thus, also in view of the limited family size in the developed countries, less than 25-30% of patients in need of an allograft can receive their transplant from an HLA-identical sibling. This percentage is even lower in patients with inherited disorders.

**HEMATOPOIETIC STEM CELL TRANSPLANTATION FROM AN HLA-IDENTICAL SIBLING DONOR**

Allogeneic HSCT from an HLA-compatible sibling is the treatment of choice for children with hematologic malignancies and congenital diseases (Table 135-1). Best results are achieved in patients with congenital or acquired non-malignant disorders because the risk of disease recurrence is low and the cumulative transplantation-related mortality is lower than in children receiving transplants for hematologic malignancies.

**ACUTE LYMPHOBLASTIC LEUKEMIA**

Allogeneic HSCT is used for pediatric patients with acute lymphoblastic leukemia (ALL), either in the first complete remission when a child is considered to be at high risk of leukemia recurrence (such as, e.g., those carrying poor-risk cytogenetic characteristics or with high levels of minimal residual disease), or in second or further complete remission after previous marrow relapse. ALL is the most common indication for HSCT in childhood. Several patient-, donor-, disease-, and transplant-related variables may influence the outcome of patients with ALL given an allogeneic HSCT. The long-term probabilities of event-free survival for patients with ALL transplanted in the 1st or 2nd complete remission is 60–70% and 40–60%, respectively. Inferior results are obtained in patients receiving transplants in more advanced disease phases. The use of radiotherapy, total body irradiation, during the preparative regimen offers an advantage in terms of better event-related risk factors for both acute and chronic GVHD.

Minor histocompatibility antigens derive from differences between the HLA-matched recipient and donor in peptides that are presented by the same HLA allotype. They are a result of polymorphisms of non-HLA proteins, of differences in the level of expression of proteins, or of genetic differences between males and females. An example of the latter is represented by the H-Y antigens encoded by the Y chromosome, which can stimulate GVHD when a female donor is employed to transplant an HLA-identical male recipient. Thus, from this evidence, it is clear that GVHD may occur even when the donor and recipient are HLA identical.

The optimal donor for any patient undergoing HSCT is an HLA-identical sibling. Because polymorphic HLA genes are closely linked and usually constitute a single genetic locus, any pair of siblings has a 25% chance of being HLA identical. Thus, also in view of the limited family size in the developed countries, less than 25-30% of patients in need of an allograft can receive their transplant from an HLA-identical sibling. This percentage is even lower in patients with inherited disorders.

**ACUTE MYELOID LEUKEMIA**

Allogeneic HSCT from an HLA-identical sibling is largely employed as postremission treatment of pediatric patients with acute myeloid leukemia (AML). In fact, many studies show that children with AML in 1st complete remission who are given allogeneic HSCT as consolidation therapy have a better probability of event-free survival than those treated with either chemotherapy alone or with autologous transplantation. Results obtained in patients given HSCT from an HLA-identical sibling after either a total body irradiation–containing or a chemotherapy-based preparative regimen are similar, the probability of event-free survival being in the order of 70%. Children with acute promyelocytic leukemia in molecular remission at the end of treatment with chemotherapy and all-trans-retinoic acid, or with AML and either translocation t(8;21) or inversion of chromosome 16 (inv16) are no longer considered eligible for allogeneic HSCT in 1st complete remission in view of their excellent prognosis with alternative treatments. Studies suggest restricting the use of HSCT to those patients with poor molecular lesions, such as FLT3-internal tandem duplication, or mixed lineage leukemia abnormalities, or with high levels of minimal residual disease at time of induction therapy. Approximately 40% of pediatric patients with AML in the second complete remission can be rescued by an allograft from an HLA-identical sibling.

**CHRONIC MYELOGENOUS LEUKEMIA**

For many yr, allogeneic HSCT has been considered to be the only proven curative treatment for children with Philadelphia-positive (Ph+) chronic myelogenous leukemia. Leukemia-free survival of chronic myelogenous leukemia patients after an allograft is 45-80%, the phase of disease (chronic phase, accelerated phase, blast crisis), recipient age, type of donor employed (either related or unrelated), and time interval between diagnosis and HSCT being the main factors influencing the outcome. The best results are obtained in children transplanted during the chronic phase from an HLA-identical sibling within 1 year from diagnosis. Treatment with the specific BCR-ABL tyrosine protein kinase inhibitors (imatinib mesylate, dasatinib,
Figure 135-1 Cumulative probability of leukemia-free survival after HLA-identical sibling bone marrow transplantation for childhood acute lymphoblastic leukemia, by pretransplantation conditioning regimen of total body irradiation (TBI) plus cyclophosphamide (CY) (upper line) or busulfan (Bu) plus cyclophosphamide (lower line). There was superior survival with the TBI plus cyclophosphamide regimen. (From Davies S, Ramsay NK, Klein JP, et al: Comparison of preparative regimens in transplants for children with acute lymphoblastic leukemia. J Clin Oncol 18:340–347, 2000.)

nilotinib), targeting the enzymatic activity of the BCR-ABL fusion protein, could modify the natural history of the disease and, thus, the indications for transplantation. Infusion of donor leukocytes can re-induce a state of complete remission in a large proportion of patients experiencing leukemia relapse.

**JUVENILE MYELOMONOCYTIC LEUKEMIA**

This is a rare hematopoietic malignancy of early childhood, representing 2–3% of all pediatric leukemias. Juvenile myelomonocytic leukemia (JMML) is characterized by hepatosplenomegaly and organ infiltration, with excessive proliferation of cells of monocytic and granulocytic lineages. Hypersensitivity to granulocyte-macrophage colony-stimulating factor and pathologic activation of the RAS-RAF-MAP (mitogen-activated protein) kinase signaling pathway play an important role in the pathophysiology. JMML usually runs an aggressive clinical course, with a median duration of survival for untreated children of <12 mo from diagnosis. Rare patients with CBL-1 or N-RAS mutations can survive for years without an allograft. HSCT is able to cure approximately 50–60% of patients with JMML. Patients who receive a transplant from an unrelated donor have a comparable outcome to those given HSCT from an HLA-compatible related donor. Cord blood transplantation represents a suitable alternative option for those patients with either a related or an unrelated donor. Leukemia recurrence is the main cause of treatment failure in children with JMML after HSCT, the relapse rate being as high as 40–50%. Because children with JMML frequently have massive spleen enlargement, splenectomy has been performed before transplantation. Spleen size at the time of HSCT and splenectomy before HSCT do not appear to affect the post-transplantation outcome. Although donor leukocyte infusion is not useful to rescue patients experiencing disease recurrence, a second allograft can induce sustained remission in approximately one-third of children with JMML relapsing after a 1st HSCT.

**MYELODYSPLASTIC SYNDROMES OTHER THAN JUVENILE MYELOMONOCYTIC LEUKEMIA**

Myelodysplastic syndromes are a heterogeneous group of clonal disorders characterized by ineffective hematopoiesis leading to peripheral blood cytopenia and a propensity to evolve toward AML. HSCT is the treatment of choice for children with refractory anemia with excess of blasts (RAEB) and for those with RAEB in transformation (RAEB-t). The probability of survival without evidence of disease for these children is 60% if the donor is an HLA-identical sibling, whereas that of patients transplanted from an alternative donor is slightly lower. It is still unclear whether patients with myelodysplastic syndromes and a blast percentage >20% benefit from pretransplantation chemotherapy. HSCT from an HLA-identical sibling is also the preferred treatment for all children with refractory cytopenia. Transplantation from an alternative donor is also employed in children with refractory cytopenia associated with monosomy 7, complex karyotype, life-threatening infections, profound neutropenia, or transfusion-dependency. For children with refractory cytopenia, the probability of event-free survival after HSCT may be as high as 80%, disease recurrence being rarely observed. This observation has provided the rationale for testing reduced-intensity regimens in these patients.

**NON-HODGKIN LYMPHOMA AND HODGKIN DISEASE**

Childhood non-Hodgkin lymphoma (NHL) and Hodgkin disease (HD) are quite responsive to conventional chemoradiotherapy, but some of these patients are at high risk for relapse. HSCT can cure a proportion of patients with relapsed NHL and HD and should be offered early after relapse, while the disease is still sensitive to therapy. If an HLA-identical sibling is available, allogeneic transplantation should be offered to patients with NHL to take advantage of the GVL effect. Patients with sensitive disease and limited tumor burden have favorable outcomes, with event-free survival rates of 50–60%. Studies also suggest that patients with HD can benefit from a GVL effect when given an allograft.

**ACQUIRED APLASTIC ANEMIA**

HSCT from an HLA-identical sibling is the treatment of choice for children with the severe form of acquired aplastic anemia, defined as 2 of the following: platelet count <20,000/mm³, absolute neutrophil count <500/mm³, or reticulocyte count <1% when anemia is present, together with hypoplastic bone marrow (<20% total cellularity). The probability of survival with sustained donor engraftment for these patients is <85–90%, younger patients having even better outcomes. Every child diagnosed with severe acquired aplastic anemia should undergo HLA-typing as early as possible in order to identify a suitable HLA-compatible family donor. Graft rejection represents the most important cause of treatment failure. Blood transfusion should be avoided whenever possible because sensitization to blood products increases the likelihood of graft rejection. GVHD prophylaxis combining cyclosporine and short-term methotrexate is associated with a better outcome as compared to cyclosporine alone (Fig. 135-2). Some studies suggest that the addition of antithymocyte globulin to the classical conditioning regimen consisting of cyclophosphamide (200 mg/kg) can reduce the risk of graft rejection, particularly in patients with previous heavy sensitization to blood products. The use of granulocyte colony-stimulating factor mobilized peripheral blood progenitors has provided inferior results with respect to the infusion of bone marrow cells, since it is associated with an increased risk of chronic GVHD.

**CONSTITUTIONAL APLASTIC ANEMIA**

Fanconi anemia and dyskeratosis congenita are genetic disorders associated with a high risk of developing pancytopenia. Fanconi anemia is an autosomal recessive disease characterized by spontaneous chromosomal fragility, which is increased after exposure of peripheral blood lymphocytes to DNA crosslinking agents, including clastogenic compounds, such as diepoxybutane, mitomycin C, and melphalan. Patients with Fanconi anemia, besides being at risk of pancytopenia, show a high propensity to develop clonal disorders of hematopoiesis, such as myelodysplastic syndromes and AML. HSCT can rescue aplastic anemia and prevent the occurrence of clonal hematopoietic disorders. In view of their defects in DNA repair mechanisms, which are responsible for the chromosomal fragility, Fanconi anemia patients have an exquisite sensitivity to alkylating agents. Thus, they must be prepared for the allograft with reduced doses of cyclophosphamide. Many patients were once successfully transplanted after receiving low-dose cyclophosphamide and thoracoabdominal irradiation. However, the use of this regimen is associated with an increased incidence of
posttransplantation head and neck cancers. Either reduced doses of cyclophosphamide alone or low-dose cyclophosphamide with fludara- bine are currently employed for preparing Fanconi anemia patients to the allograft. Using these regimens, the success rate of HSCT from an HLA-identical sibling is on the order of 70-80%. Results of unrelated donor allograft have markedly improved over time and rival with those obtained using an HLA-identical sibling donor.

Allogeneic HSCT remains the only potentially curative approach for severe bone marrow failure associated with dyskeratosis congenita, a rare congenital syndrome characterized also by atrophy and reticular pigmentation of the skin, nail dystrophy, and leukoplakia of mucous membranes. Results of allograft in these patients have been relatively poor, due to occurrence of both early and late complications, reflecting increased sensitivity of endothelial cells to radiotherapy and alkylating agents.

THALASSEMIA

Conventional treatment (i.e., regular blood transfusion and iron-chelation therapy) has dramatically improved both the survival and quality of life of patients with thalassemia, changing a previously fatal disease with early death to a chronic, slowly progressive disease compatible with prolonged survival. However, HSCT remains the only curative treatment for patients with thalassemia. In patients with thalassemia, the risk of dying from transplant-related complications is primarily dependent on patient age, iron overload, and concomitant hepatic viral infections. Adults, especially when affected by chronic active hepatitis, have a poorer outcome than children. Among children, 3 classes of risk have been identified on the basis of 3 parameters, namely regularity of previous iron chelation, liver enlargement, and presence of portal fibrosis. In pediatric patients without liver disease who have received regular iron chelation (class 1 patients), the probability of survival with transfusion independence is >90%, whereas for patients with low compliance with iron chelation and signs of severe liver damage (class 3 patients), the probability of survival is 60% (Fig. 135-3). As in other nonmalignant disorders the most effective pharmacologic combinations (such as that including cyclosporine and methotrexate) should be employed to prevent GVHD. The outcome of patients transplanted from an unrelated donor has been reported to be similar to that of HLA-identical sibling recipients.

SICKLE CELL DISEASE

Disease severity varies greatly among patients with sickle cell disease, with 5-20% of the overall population suffering significant morbidity from vasoocclusive crises and pulmonary, renal, or neurologic damage. Despite the fact that hydroxyurea, an agent favoring the synthesis of fetal hemoglobin, reduces the frequency and severity of vasoocclusive crises and improves the quality of life for patients with sickle cell disease, allogeneic HSCT is the only curative treatment for this disease. Although HSCT can cure homozygous hemoglobin S disease, selecting appropriate candidates for transplantation is difficult. Patients with sickle cell disease may survive for decades, but some patients have a poor quality of life, with repeated hospitalizations for painful vasoocclusive crises and central nervous system infarcts. The main indications for performing HSCT in patients with sickle cell disease are history of strokes, magnetic resonance imaging of central nervous system lesions associated with impaired neuropsychologic function, failure to respond to hydroxyurea as shown by recurrent acute chest syndrome, and/or recurrent vasoocclusive crises and/or severe anemia and/or osteonecrosis. The results of HSCT are best when performed in children with an HLA-identical sibling, with a probability of cure of 80-90%. The use of antithymocyte globulin during the preparative regimen improves patient outcome, dramatically reducing the risk of graft failure.

IMMUNODEFICIENCY DISORDERS

HSCT is the treatment of choice for children affected by severe combined immunodeficiency, as well as for other inherited immunodeficiencies, including Wiskott-Aldrich Syndrome, leukocyte adhesion deficiency, and chronic granulomatous disease (see also Table 135-1 for details), among others. With an HLA-identical sibling, the probability of survival approaches 100%, with less-favorable results for patients transplanted from an HLA-partially matched related. Some children with severe combined immunodeficiency, mainly those without residual natural killer activity or maternal T-cell engraftment, may be transplanted without receiving any preparative regimen, the donor lymphoid cells usually being the only elements that engraft. Sustained donor engraftment is more difficult to achieve in children with Omenn syndrome, hemophagocytic lymphohistiocytosis, or leukocyte adhesion deficiency. Life-threatening opportunistic fungal and viral infections occurring before the allograft adversely affect the patient's outcome after HSCT. Patients with the most severe immunodeficiencies must be transplanted as early as possible.

Bibliography is available at Expert Consult.
Bibliography

Two-thirds of patients who need allogeneic hematopoietic stem cell transplantation (HSCT) do not have an available human leukocyte antigen (HLA)-identical sibling. Alternative donor/sources of hematopoietic stem cells are being increasingly used and include: matched unrelated donors, unrelated umbilical cord blood (UCB), and HLA-haploidentical relatives. Each of these 3 options has advantages and limitations, but rather than being considered competing alternatives, they should be regarded as complementary strategies to be chosen after a careful evaluation of the relative risks and benefits in the patient’s best interest. The choice of the donor will depend on various factors related to urgency of transplantation, patient-, disease-, transplant-related factors and center experience. Physician preference is expected to influence this choice as well.

UNRELATED DONOR TRANSPLANTS
One of the most widely used strategies for children who need an allograft and do not have an available HLA-identical sibling is to identify an unrelated HLA-matched donor in a registry. Today, worldwide international registries include more than 20 million HLA-typed volunteer donors. HLA-A, -B, -C class I loci, and the DRB1 class II locus are the HLA loci most influencing outcome after HSCT from an unrelated volunteer. The roles played by other class II loci (namely, DQB1 and DP1 loci) on patient outcome remain controversial.

Data on serologic typing of HLA classes IA and IB loci are available for all donors, and there is information on DRB1 typing for approximately one-third of donors. Although in the past serologic (low-resolution) typing was used for HLA-A and -B loci, currently, the unrelated donors are selected using high-resolution (allelic) molecular typing of loci HLA-A, -B, -C, and -DRB1. The chance of finding an HLA-matched donor depends on the frequency of the HLA phenotype, which is closely linked to the ethnic origin of the registry donors and ranges from 60-70% for white patients to <10% for persons of other ethnic groups (Hispanic, black, etc.).

Identifying a suitable unrelated donor is a complicated and lengthy process, the median time elapsing from the start of search to transplantation being 3-4 mo. During this period, a patient with acute leukemia may relapse and require further therapy, accumulating organ toxicity that unfavorably affects outcome. Moreover, for various different reasons, a relevant proportion of donors (sometimes reaching 10-20%) are either no longer available or refuse donation. Despite these limitations, many thousands of matched unrelated donor transplantations have been performed.

Initially, HLA polymorphism and the intrinsic limitations of conventional (i.e., serologic) HLA-typing techniques unfavorably affected the accuracy of matching, thus increasing rejection rates and the incidence of acute and chronic graft-versus-host disease (GVHD). Consequently, because the event-free survival of recipients of an unrelated donor allograft was worse than that observed when the donor was a compatible sibling transplant, there is no consensus on the use of unrelated donor transplants for nonmalignant diseases, such as thalassemia or primary immune deficiency syndromes other than severe combined immunodeficiency (SCID). DNA-based (i.e., high-resolution molecular) techniques for HLA typing have revealed an impressive number of new alleles within antigens that were previously defined by serology only. Matching by high-resolution DNA typing reduces the risk of immune complications, namely graft rejection and GVHD, but also the chance of finding a suitable donor. Nevertheless, the advent of both high-resolution molecular HLA classes I and II loci-typing coupled with progress in the prophylaxis and treatment of GVHD has resulted in a reduction of transplantation-related mortality and improvement of outcome. Indeed, outcomes from a fully matched unrelated volunteer donor are now similar to those of HSCT from an HLA-identical sibling, as indicated by results of unrelated donor transplantation in children with acute lymphoblastic leukemia in second complete remission, juvenile myelomonocytic leukemia, or thalassemia (Fig. 136-1).

Although a single locus disparity in patients with leukemia does not markedly affect the probability of event-free survival as the increased risk of toxic death may be compensated for by a reduction in the relapse rate, in patients with nonmalignant disorders optimal results are obtained only when a donor matched at the allelic level with the recipient is selected. In general, a single HLA disparity in the donor–recipient pair, irrespective of whether antigenic or allelic in nature, predicts a greater risk of nonleukemia mortality; multiple allelic disparities at different HLA loci have an additive detrimental effect and are associated with an even worse outcome. To reduce the risk of acute GVHD, ex vivo T-cell depletion of the graft has been employed, but has not significantly affected patient outcome, which is similar to that of patients given an unmanipulated graft and pharmacologic prophylaxis for GVHD.

The analyses on the outcome of unrelated donor HSCT include only patients who are transplanted; these numbers do not take into account patients for whom a donor is not found. For patients who urgently need a transplant, the time required to identify a suitable donor from a potential panel, establish eligibility, and harvest the cells may lead to relapse and failure to transplant. For patients who do not have a matched donor or who urgently need a transplant, attention has focused on unrelated cord blood and HLA-haploidentical, mismatched family donors.

UMBILICAL CORD BLOOD TRANSPLANTS
UCB transplantation (UCBT) is a viable option for children who need allogeneic HSCT. To date, several hundred children have been cured...
through transplantation of either related or unrelated UCB units. UCBT offers the advantages of absence of risks to donors, reduced risk of transmitting infections, and, for transplants from unrelated donors, immediate availability of cryopreserved cells, the median time elapsing from start of search to transplantation being only 3-4 wk. In comparison to bone marrow transplantation (BMT), the advantages of UCBT are also represented by lower incidence and severity of GVHD, easier procurement and prompter availability of cord blood cells, and the possibility of using donors showing HLA disparities with the recipient. Despite these advantages, the large experience gained over the last 2 decades has clearly demonstrated that UCBT patients may be exposed to an increased risk of early fatal complications, mainly because of a lower engraftment rate of donor hematopoiesis, delayed kinetics of neutrophil recovery, and lack of adoptive transfer of pathogen-specific memory T-cells. In fact, transfer of donor-derived, memory T cells significantly contributes to early immunologic reconstitution of children after unmanipulated allogeneic bone marrow or peripheral blood stem cell transplantation.

Concerning the issues of engraftment and hematopoietic recovery, it has been unquestionably shown that an inverse correlation between the number of nucleated cord blood cells infused per kilogram recipient body weight and the risk of dying for transplantation-related causes exists. In particular, engraftment is a major concern when the nucleated cells are \(<2.5 \times 10^7/\text{kg of recipient body weight}. As a cord blood unit usually contains between 1 \times 10^8 and 1.8 \times 10^8 cells, it is not surprising that UCB transplantation has been less frequently employed for adolescents or adults with body weight >40 kg. Indeed, it can be estimated that only 30% of the UCB units available in the bank inventory could suffice for a 75 kg patient according to the recommended threshold old cell dose (namely more than 2.5 \times 10^7 total nucleated cells/kg recipient body weight before thawing the unit). In view of these findings, it is not surprising that efforts have been focused on approaches capable of increasing the number of UCB cells to be transplanted. Selection of the richest cord blood units, infusion of 2 units in the same recipient (i.e., double UCBT), and transplantation of ex vivo expanded progenitors have contributed to improve the results of UCBT, opening new scenarios for a wider application of the procedure. In particular, double UCBT is largely employed as it was demonstrated to be effective in adults, significantly increasing the engraftment rate, as compared to single-unit UCBT. In the majority of double UCBT, the 2 UCB units are partially HLA-matched with the recipient, as well as with each other, and sustained hematopoiesis after double UCBT is usually derived from a single donor. This technique is of interest to pediatricians for extending the applicability of UCBT also to adolescents or to patients with a body weight exceeding 40-50 kg.

Direct intrabone transplantation of UCB cells is also a feasible and safe approach, able to overcome the problem of graft failure, even when low numbers of HLA-mismatched cord-blood cells are transplanted, and to guarantee prompt platelet recovery. Despite the low incidence of acute and chronic GVHD observed after UCB transplantation, the risk of recurrence of leukemia is not increased. The long-term results of UCB transplants are similar to those after transplantation from other sources of hematopoietic stem cells. In particular, several published reports have compared the outcome of UCBT and BMT from unrelated donors in children with hematologic malignancies. Recipients of UCBT were transplanted from donors with greater HLA-disparities, received 1-log fewer nucleated cells, had delayed neutrophil and platelet recovery, and showed reduced incidence of GVHD as compared to children given BMT. Nevertheless, both the relapse rate and the overall survival probability did not differ in unrelated UCBT or BMT pediatric recipients. The outcome of patients receiving a fully matched UCB unit is reported to be even better than that of patients who receive a transplant from an HLA-identical, unrelated volunteer. Thus, today, there is no doubt that, in the absence of an HLA-identical family donor, unrelated UCBT can be considered a suitable option for children with malignant and non-malignant disorders. Results of UCBT have been of particular interest in children with Hurler syndrome or Krabbe disease transplanted with cord blood cells from an unrelated donor, as well as in children with hemoglobinopathies given a related UCB transplantation. It has to be emphasized that the lower risk of GVHD associated with UCBT is of particular importance in patients affected by nonmalignant disorders.

Approximately 5% of patients receiving UCB transplantation develop an autoimmune disorder. These disorders include autoimmune hemolytic anemia, autoimmune thrombocytopenia, Evans syndrome, and immune neutropenia. Less frequently, patients have developed Graves disease, glomerulonephritis, rheumatoid arthritis, or thyroiditis. Treatment for these post-UCB transplant-related autoimmune diseases has included steroids, rituximab, and cyclosporine, with only varying degrees of success.

**HAPLOIDENTICAL TRANSPLANTS**

HSCT from an HLA-haploidentical (haplo-HSCT) donor offers an immediate source of hematopoietic stem cells to almost all leukemia patients who fail to find a matched donor, whether related or unrelated, or a suitable cord blood unit. Indeed, almost all children have at least 1 haploidentical–3 loci mismatched family member who is promptly available as donor. Moreover, the few patients who reject the haploidentical transplant have the advantage of another immediately available donor within the family.

Efficient T-cell depletion of the graft has been demonstrated to prevent acute and chronic GVHD even when using haploidentical parental bone marrow differing at the 3 major HLA loci. The benefits of T-cell depletion were first demonstrated in transplantation of children with SCID. More than 300 transplants in SCID patients using haploidentical donors have been performed worldwide, with a high rate of long-term partial or complete immune reconstitution. As patients with acute leukemia have a high chance of rejecting a haploidentical bone marrow graft, a “megadose” of granulocyte colony-stimulating factor–mobilized peripheral blood stem cells has been demonstrated to be crucial for overcoming the barrier of HLA incompatibility in the donor–recipient pair and for eluding residual antidonor cytotoxic T-lymphocyte precursor activity in the recipient. Indeed, in leukemia patients, the combination of high-intensity immune-suppressive/myeloablative conditioning regimens with the infusion of great numbers of highly purified, peripheral blood CD34+ cells has been demonstrated capable to (1) guarantee the successful and sustained engraftment of donor haematopoiesis across the HLA barrier, and (2) guarantee a very low incidence of grades II-IV acute GVHD without the need for any posttransplantation immune suppression as prophylaxis. The physical elimination of mature T cells from the graft, necessary for preventing GVHD occurrence in a context of great immune genetic disparity, leads to the consequence that recipients cannot benefit from the adoptive transfer of donor memory T lymphocytes that, through their peripheral expansion, are the main factor responsible for protection from infections in the 1st few mo after transplantation. A state of profound immune deficiency lasts for at least 4-6 mo after transplantation in haplo-HSCT recipients. Sophisticated strategies of adoptive infusions of T-cell lines or clones specific for the most common and life-threatening pathogens (namely Epstein-Barr virus, human cytomegalovirus, Aspergillus, and adenovirus) have been envisaged and successfully tested in a few pilot trials to protect the recipients in the early posttransplantation period. Selective approaches of graft manipulation have also been developed. In particular, promising results have been obtained through a negative depletion of T lymphocytes carrying the \( \alpha/\beta \) chains of the T-cell receptor. B-lymphocytes are also depleted to prevent the occurrence of Epstein-Barr virus–related lymphoproliferative disease. Through this approach the patient can benefit from the adoptive transfer of committed hematopoietic progenitors, mature natural killer (NK) cells and \( \gamma/\delta \) T cells, which can confer a protection against life-threatening infections.

The outcomes of haplo-HSCT have been more extensively reported in adults than in children. The reported probability of survival at 3-4 yr after a haplo-HSCT in children with acute leukemia ranged from 18-48%. Survival was influenced by many factors, the most important being the state of remission at time of transplantation, with poorer outcomes in children with myeloid leukemias than in those with lymphoid leukemia. It has been reported that in haplotype mismatched
parent-to-child HSCT, patients with acute leukemia grafted from the mother had reduced relapse rates as compared with recipients of paternal grafts, translating into better event-free survival.

For many years the absence of the T-cell mediated graft-versus-leukemia (GVL) effect has been considered rendering the recipients of a T-cell depleted allograft more susceptible to leukemia relapse. However, it has been demonstrated that a GVL effect displayed by donor NK cells can compensate for this lack of T-specific alloreactivity when an HLA-disparate NK alloreative relative is employed as a donor.

**DONOR VERSUS RECIPIENT NATURAL KILLER–CELL ALLOREACTIVITY**

Donor vs recipient NK-cell alloreactivity is a biologic phenomenon that is unique to the mismatched transplant. It derives from a mismatch between donor NK clones, carrying specific inhibitory receptors for self-major histocompatibility complex (MHC) class I molecules, and MHC class I ligands on recipient cells. NK cells are primed to kill by several activating receptors, which play an important role in the NK cell-mediated GVL effect. Human NK cells discriminate allelic forms of MHC molecules via killer cell immunoglobulin-like receptors (KIRs), which are clonally distributed with each cell in the repertoire bearing at least 1 receptor that is specific for self-MHC class I molecules. Because NK cells coexpress inhibitory receptors for self-MHC class I molecules, autologous cells are not killed. When faced with mismatched allelic targets, NK cells sense the missing expression of self-class I alleles and mediate alloreactions. In mismatched transplant, there are many donor recipient pairs in which the donor NK inhibitory cells do not recognize the recipient's class I alleles as self. Consequently, the donor NK cells are not blocked and are activated to lyse the recipient's lymphohematopoietic cells.

Haplo-HSCT trials demonstrate that MHC class I mismatches, which generate an alloreactive NK cell response in the graft-versus-host reaction, eradicate leukemia cells, improve engraftment, and protect from T-cell-mediated GVHD. Lack of an NK-alloreactive donor is the strongest independent risk factor for leukemia relapse after adjustment for disease status at transplantation. The potential for donor vs recipient NK cell alloreactivity, which can be predicted by standard HLA typing, is recommended when selecting the donor of choice from among the mismatched family members.

The chance of finding a "perfect mismatch" NK-alloreactive donors in the family is on the order of 50%. From a practical point of view, first, the transplantation candidate is HLA typed. Candidates expressing class I alleles belonging to the 3 class I groups recognized by KIRs (HLA-C group 1, HLA-C group 2, and HLA-Bw4 alleles) will block all NK cells from every donor and belong to the one-third of the population that is resistant to alloreactive NK killing. Patients who express only 1 or 2 of these allele groups may find NK-alloreactive donors.

Donor HLA typing identifies family members who do not express the class I group(s) expressed by the patient and, therefore, have the potential for NK alloreactivity. Not all inhibitory KIRs are present in 100% of the population. KIR2DL2/3, the receptor for HLA-C group 1, is present in all persons; KIR2DL1, the receptor for HLA-C group 2, is present in 97% of persons; and KIR3DL1, the receptor for HLA-Bw4 alleles, is present in ~90%. Donor KIR genotyping ensures that the donor expresses the relevant NK cells.

In HLA-Bw4 mismatches, even when the KIR3DL1 gene is present, NK repertoire studies show alloreactive NK cells in approximately two-thirds of individuals. This may be because they occur in highly variable frequencies or because allelic KIR3DL1 variants may not allow receptor expression at the cell membrane. Therefore, for HLA-Bw4 mismatches, direct assessment of the donor NK repertoire is necessary.

**AUTOLOGOUS HEMATOPOIETIC STEM CELL TRANSPLANTATION**

Autologous transplantation, using the patient's own stored marrow, is associated with a low risk of life-threatening transplant-related complications, although the main cause of failure is disease recurrence resulting from a lack of the immune-mediated GVL effect. Bone marrow was once the only source of stem cells employed in patients given an autograft; in the past few years, the vast majority of patients treated with autologous HSCT receive hematopoietic progenitors mobilized in peripheral blood by either cytokines (mainly granulocyte colony-stimulating factor) or by cytokines plus cytotoxic agents. A CXC4R4 antagonist (plerixafor) can be extremely effective in mobilizing hematopoietic progenitors in the periphery. When compared to bone marrow, the use of peripheral blood progenitors is associated with a faster hematopoietic recovery and a comparable outcome. A major concern in patients with malignancies given autologous HSCT is represented by the risk of reinfusing malignant cells with the graft; tumor progenitors contained in the graft can contribute to recurrence of the original malignant disease. This observation has provided the rational for tumor purging using elaborated strategies aimed at reducing or eliminating tumor contamination of the graft.

Autologous HSCT is employed primarily to prevent relapse in patients with acute myelogenous leukemia (AML) who achieve complete remission after induction therapy, and also for selected children with relapsed lymphomas and selected solid tumors (Table 136-1).

Randomized studies have not shown an advantage in terms of event-free survival for patients with AML in the 1st complete remission given an autologous HSCT as compared to those treated with chemotherapy alone. The probability of event-free survival for children with AML in the 1st complete remission given autologous HSCT is reported to range from 40-60%. Ex vivo purging of bone marrow cells with mafosfamide has been shown to reduce the risk of disease recurrence in children with AML in the 1st complete remission given an autologous transplantation.

Patients with sensitive lymphomas and little tumor burden have favorable outcomes after autologous HSCT, with disease-free survival rates of 50-60%, whereas high-risk patients with bulky tumor or poorly responsive disease have a dismal outcome, with survival rates of 10-20%.

Some studies suggest that, as compared to conventional chemotherapy and radiotherapy, autologous HSCT may offer an advantage in terms of event-free survival to children with acute lymphoblastic leukemia in the second complete remission after an isolated extramedullary relapse (i.e., central nervous system, testicular relapse).

Autologous HSCT in patients with high-risk neuroblastoma is associated with a better outcome compared to conventional chemotherapy. In these patients, posttransplantation infusion of a monoclonal antibody directed against a molecule (GD2) expressed on the surface of neuroblastoma cells confers a protection against the risk of tumor recurrence.

For children with brain tumors at high risk of relapse, or resistant to conventional chemotherapy and irradiation, the dose-limiting toxicity for intensifying therapy is myelosuppression, thus providing a role for stem cell rescue. Several studies provide encouraging results for patients with different histologic types of brain tumors treated with autologous HSCT.

Clinical Staging and Grading of Graft-Versus-Host Disease

Acute GVHD usually develops from 2-8 wk posttransplantation. The primary manifestations are an erythematous maculopapular rash, persistent anorexia, vomiting and/or diarrhea, and liver disease with increased serum levels of bilirubin, alanine aminotransferase, aspartate aminotransferase, and alkaline phosphatase (Table 137-1). Diagnosis may benefit from skin, liver, or gastrointestinal biopsy for confirmation. Endothelial damage and lymphocytic infiltrates are seen in all affected organs. The epidermis and hair follicles of the skin are damaged, the hepatic small bile ducts show segmental disruption, and there is destruction of the crypts and mucosal ulceration of the gastrointestinal tract. Grade I acute GVHD (skin rash alone) has a favorable prognosis and often does not require treatment (Fig. 137-1). Grade II GVHD is a moderately severe multiorgan disease requiring immunosuppressive therapy. Grade III GVHD is a severe multiorgan disease, and grade IV GVHD is a life-threatening, often fatal condition. The standard pharmacologic prophylaxis of GVHD after an unmanipulated allograft relies mainly on posttransplant administration of immunosuppressive drugs, such as cyclosporine or tacrolimus or combinations of either with methotrexate or prednisone, anti–T-cell antibodies, mycophenolate mofetil, and other immunosuppressive agents. Infusion of cyclophosphamide on days +3 and +5 after transplantation has been proposed as a strategy to delete alloreactive donor T lymphocytes that become activated, and thus cycling, after exposure to recipient antigens. Pretransplantation infusion of either antithymocyte globulin or monoclonal antibodies such as alemtuzumab is largely used to modulate alloreactivity of donor T cells, in particular in patients given the allograft from either an unrelated donor or a partially matched relative. An alternative approach, which has been widely used in clinical practice, is the removal of T lymphocytes from the graft (T-cell depletion). Any form of GVHD prophylaxis in itself may impair posttransplantation immunologic reconstitution, increasing the risk of infection-related deaths. T-cell depletion of the graft is also associated with an increased risk of leukemia recurrence in patients transplanted from an human leukocyte antigen (HLA)-identical sibling or an unrelated volunteer.

Despite prophylaxis, significant acute GVHD develops in ≈30% of recipients of HSCT from matched siblings and in as many as 60% of HSCT recipients from unrelated donors. The risk of acute GVHD is increased by factors such as diagnosis of malignant disease, older donor and recipient ages, and, in patients given an unmanipulated allograft, GVHD prophylaxis including only 1 drug. However, the most important risk factor for acute GVHD is the present of disparities for HLA-molecules in the donor-recipient pair. Acute GVHD is usually initially treated with glucocorticoids; approximately 40-50% of patients show a complete response to steroids. The risk of transplantation-related mortality is much higher in patients who do not respond to

Chronic GVHD develops or persists >3 mo posttransplantation and is the most frequent late complication of allogeneic HSCT with an incidence of ≈25% in pediatric patients. Chronic GVHD is the major cause of nonrelapse mortality and morbidity in long-term HSCT survivors. Acute GVHD is recognized as the most important factor predicting the development of the chronic form of the disease. The use of matched unrelated volunteers as donors, and of peripheral blood as the stem cell source, has increased the incidence and severity of chronic GVHD. Other factors that predict occurrence of chronic GVHD include older donor and recipient ages, female donor for male recipient, diagnosis of malignancy, and use of total-body irradiation as part of the preparative regimen.

Chronic GVHD is a disorder of immune regulation characterized by autoantibody production, increased collagen deposition and fibrosis, and clinical symptoms similar to those seen in patients with autoimmune diseases. The predominant cytokines involved in the pathophysiology of chronic GVHD are usually type II cytokines such as IL-4, IL-5, and IL-13. IL-4 and IL-5 contribute to B-cell hyperactivity with elevated immunoglobulin (Ig) M, IgG, and IgE titers. Associated monoclonal gammapathies indicate clonal dysregulation. Chronic GVHD is dependent on the development and persistence of donor T cells that are not tolerant to the recipient. Maturation of transplanted stem cells within a damaged thymus could lead to errors in negative selection and production of cells that have not been tolerated to recipient antigens and are, therefore, autoreactive or, more accurately, recipient reactive. This ongoing immune reactivity results in clinical features resembling a systemic autoimmune disease with lichenoid and sclerodermatous skin lesions, malar rash, sicca syndrome, arthritis, joint contractures, obliterator bronchiolitis, and bile duct degeneration with cholestasis.

Patients with chronic GVHD involving only the skin and liver have a favorable course (Fig. 137-2). Extensive multorgan disease may be associated with a very poor quality of life, recurrent infections associated with prolonged immunosuppressive regimens to control GVHD, and a high mortality rate. Morbidity and mortality are highest in patients with a progressive onset of chronic GVHD that directly follows acute GVHD, intermediate in those with a quiescent onset after resolution of acute GVHD, and lowest in patients with de novo onset in the absence of acute GVHD. Single-agent prednisone is standard treatment at present, although other agents, including extracorporeal photopheresis, mofetil mycophenolate, anti-CD20 monoclonal antibody, and pentostatin, have been employed with variable success. Treatment with imatinib mesylate, which inhibits the synthesis of collagen, has been shown to be effective in patients with chronic GVHD and sclerotic features. As a consequence of prolonged immunosuppression, patients with chronic GVHD are particularly susceptible to infections and should receive appropriate antibiotic prophylaxis, including trimethoprim-sulfamethoxazole. Chronic GVHD resolves in most pediatric patients but may require 1-3 yr of immunosuppressive therapy before the drugs can be withdrawn without the disease recurring. Chronic GVHD promotes also the development of secondary neoplasms, in particular in patients with Fanconi anemia.

Graft failure is a serious complication exposing patients to a high risk of fatal infection. Primary graft failure is defined as failure to achieve a neutrophil count of 0.2 × 10^9/L by 21 days posttransplantation. Secondary graft failure is loss of peripheral blood counts following initial transient engraftment of donor cells. Causes of graft failure after autologous and allogeneic transplantation include transplantation of an inadequate stem cell dose (more frequently observed in children given cord blood transplantation), and viral infections such as with cytomegalovirus or human herpesvirus type 6, which are often associated with activation of recipient macrophages. Graft failure after allogeneic transplantation, however, is mainly caused by immunologically mediated rejection of the graft by residual recipient-type T cells that survive the conditioning regimen. Diagnosis of graft failure resulting from immunologic mechanisms is based on examination of peripheral blood and marrow aspirate and biopsy, along with molecular analysis of chimerism status. Persistence of lymphocytes of host origin in allogeneic transplant recipients with graft failure indicates immunologic
rejection. The risk of immune-mediated graft rejection is higher in patients given HLA-disparate, T-cell–depleted grafts, reduced-intensity conditioning regimens, and transplantation of low numbers of stem cells, and in recipients who are sensitized toward HLA antigens or, less frequently, minor histocompatibility antigens. Allosensitization develops as a consequence of preceding blood product transfusions and is observed particularly in recipients with aplastic anemia, sickle cell disease, and thalassemia. In HSCT for nonmalignant diseases, such as mucopolysaccharidoses, graft failure is also facilitated by the absence of previous treatment with cytotoxic and immunosuppressive drugs. In thalassemia, graft failure is promoted by expansion of recipient hematopoietic cells. GVHD prophylaxis with methotrexate, an antimetabolite, and antiinfective prophylaxis with trimethoprim-sulfamethoxazole or ganciclovir may also delay engraftment.

**Treatment** of graft failure usually requires removing all potentially myelotoxic agents from the treatment regimen and attempting a short trial of hematopoietic growth factors, such as granulocyte colony-stimulating factor. A second transplant, usually preceded by a highly immune-suppressive regimen, is frequently employed to rescue patients experiencing graft failure. High-intensity regimens are generally tolerated poorly if administered within 100 days from a 1st transplant because of cumulative toxicities.

**VENOOCCLUSIVE DISEASE**

Hepatic venoocclusive disease, also known as sinusoidal obstruction syndrome, presents with hepatomegaly, right upper quadrant tenderness, jaundice, and weight gain from fluid retention and ascites. Onset is usually within 30 days of transplantation, with an incidence of approximately 15%, depending on the intensity of the conditioning protocol. Risk factors include young age, prior hepatic disease (fibrosis, cirrhosis), abdominal radiation, repeated transplantations, neuroblastoma, osteopetrosis and familial hemophagocytic lymphohistiocytosis. The severe form of venoocclusive disease has a high mortality rate; treatment results for severe disease are poor.

Prophylaxis has traditionally used heparin and ursodeoxycholic acid; however, only defibrotide has demonstrated some efficacy in preventing venoocclusive disease. Defibrotide is a combination of porcine oligodeoxyribonucleotides that reduces procoagulant activity and enhances fibrinolytic properties of endothelial cells.

Bibliography
Hematopoietic stem cell transplantation (HSCT) recipients experience a transient but profound state of immune deficiency. Immediately after transplantation, because neutrophils are absent or markedly reduced, patients are particularly susceptible to bacterial and fungal infections. Consequently, most centers start prophylactic antibiotic or antifungal treatment during the conditioning regimen. Despite these prophylactic measures, most patients will develop fever and signs of infection in the early posttransplantation period. The common pathogens include enteric bacteria and fungi such as *Candida* and *Aspergillus*. An indwelling central venous line, routinely employed in all children given HSCT, is a significant risk factor for bacterial and fungal infections, staphylococcal species and *Candida* being the most frequent pathogens in catheter-related infections (see Chapter 178). Emergence of multidrug resistant strains of *Pseudomonas aeruginosa* and *Klebsiella pneumoniae* has become a serious problem, being associated with a high case: fatality ratio.

HSCT recipients remain at increased risk of developing severe infections even after the neutrophil count has normalized, because T-cell number and function remain below normal for months after transplantation. Unrelated donor transplant recipients are at increased risk of developing graft-versus-host disease (GVHD), which is itself an additional risk factor for fungal and viral opportunistic infections, as are the associated immunosuppressive treatments. After cord blood transplantation, infections are the consequence of both the slow neutrophil engraftment and donor T-cell naïveté. In haploidentical transplantation, the increased risk of infection observed in the 1st 4-6 mo after the allograft is the consequence of T-cell depletion of the graft. Indeed, patients given this type of transplantation, as well as those receiving cord blood transplantation, cannot benefit from the adoptive transfer of donor-derived, antigen-experienced T cells.

Among HSCT recipients, invasive aspergillosis, cytomegalovirus (CMV) infection, disseminated adenovirus infections, and Epstein-Barr virus (EBV)-related lymphoproliferative disorders represent peculiar, life-threatening complications that significantly affect patients’ outcome.

Invasive *aspergillosis* remains a significant cause of infectious morbidity and mortality in HSCT recipients. Despite prompt and aggressive administration of potent antifungal agents, proven cases of aspergillosis remain difficult to treat, with case-fatality rates of 80-90%. The annual incidence of invasive aspergillosis has risen with use of stem cells from alternative sources. The incidence is 7.3% in recipients of an human leukocyte antigen (HLA)-matched related donor transplant and 10.5% in patients given the allograft from either an HLA-mismatched family donor or an unrelated donor volunteer. Most cases of aspergillosis are diagnosed from 40-180 days after HSCT, with 30% diagnosed <40 days before and 17% more than 6 mo after transplantation. The risk of developing aspergillosis is mainly influenced by the duration of neutropenia, GVHD occurrence, use of corticosteroid therapy, posttransplant CMV infection, viral respiratory tract infections, advanced disease status, older age, and T-cell depletion of the graft. Patients with a previous history of invasive aspergillosis are at particular risk.

*Aspergillus* infection often originates from the upper airway mucosa. Early lesions in the nose should be sought in patients with neutropenia who have fever and minimal epistaxis. Rapid extension into the adjacent paranasal sinuses, orbit, or face is usual, with or without the appearance of lung lesions. In the lung, invasive aspergillosis generally presents as an acute, rapidly progressive, densely consolidated pulmonary infiltrate. Infection progresses by direct extension across tissue and by hematogenous dissemination to brain and other organs. The earliest CT finding is one or more small pulmonary nodules. As a nodule enlarges, the dense central core of infarcted tissue becomes surrounded by edema or hemorrhage, forming a hazy rim, the *halo sign*. This rim disappears in a few days as the dense core enlarges. In neutropenic patients, when bone marrow function recovers, the infarcted central core cavitates, creating the *crescent sign*. Repeated positivity for serum galactomannan represents a useful biomarker for confirming/suspecting a diagnosis of invasive aspergillosis. Antifungal prophylaxis includes isolation of the patient in a laminar air flow or positive pressure room. Liposomal amphotericin B, azole compounds (itraconazole, voriconazole, posaconazole) and echinocandins (caspofungin, micafungin, anidulafungin) are useful for both preventing and treating the fungal infection. Voriconazole represents the treatment of choice for patients with invasive pulmonary and brain aspergillosis. However, often, aspergillosis does not respond satisfactorily to antifungal agents alone, and patients remain at risk until T-cell counts and function recover. This observation provides the rationale
for developing strategies to accelerate the recovery of pathogen-specific immune responses.

**CMV infection** remains the most common and potentially severe viral complication in patients given allogeneic HSCT. Seropositivity for CMV is an independent risk factor for mortality, even in recipients of matched sibling or unrelated donor transplants. CMV is itself immunosuppressive, as it impairs dendritic cell and T-lymphocyte function. Moreover, ganciclovir, the most frequently used anti-CMV agent, may cause leukopenia and T-cell immune suppression.

The period of maximal risk for CMV infection is 1-4 mo after transplantation. Until CMV-specific T-cell responses develop months after transplant, CMV infection may result in a variety of syndromes including fever, leukopenia, thrombocytopenia, hepatitis, pneumonitis, retinitis, esophagitis, gastritis, and colitis. CMV pneumonia, the most life-threatening complication related to viral infection, has been reported to occur in up to 15-20% of bone marrow transplant recipients, with a case fatality rate of 85%. The risk is greatest between 5 and 13 wk after transplantation. Risk factors include T-cell depletion of the graft, donor seronegative status together with recipient seropositive status, acute GVHD, and patient older age.

Tachypnea, hypoxia, and unproductive cough signals respiratory involvement. Chest x-ray often reveals bilateral interstitial or reticulonodular infiltrates, which begin in the periphery of the lower lobes and spread centrally and superiorly. The differential diagnosis includes infection with *Pneumocystis jiroveci* or other viral, bacterial, or fungal pathogens, pulmonary hemorrhage, and injury secondary to irradiation or to treatment with cytotoxic drugs. Gastrointestinal CMV involvement may lead to ulcers of the esophagus, stomach, small intestine, and colon that may result in bleeding or perforation.

Fatal CMV infections are often associated with persistent viremia and multiorgan involvement. In the 1980s, antiviral treatment was deferred until overt clinical symptoms of CMV infection developed, which led to a high incidence of fatal events. CMV disease has largely been prevented through prophylaxis and a preemptive approach. Prophylaxis is based on administration of antiviral drugs to all transplanted patients for a median duration of 3 mo after transplantation. The major drawbacks of this approach refer to drug toxicity, occurrence of late CMV disease, mainly pneumonia, after withdrawal of prophylaxis, treatment of patients who do not need antiviral therapy as they would not have reactivated CMV infection, and low cost-effectiveness. Preemptive, or presymptomatic, therapy aims at treating only patients who experience CMV reactivation and, thus, are at risk of developing overt disease; it starts only upon detection of CMV in blood by any assay. The most widely used assay is CMV detection of CMV DNA in blood, which have been used to decide inception of treatment when it either becomes positive or reaches a predetermined threshold. Although in the past treatment usually started after this assay became positive, nowadays therapy is usually initiated when a certain viral load is reached. Moreover, quantification of CMV DNA in blood provides a reliable approach for deciding interruption of treatment. The major drawback of this strategy is the need of serial monitoring that is required for the period in which patients are at risk of developing CMV disease. In this regard, approaches to reliably prove the restoration of virus-specific immunity have been developed. Generally, ganciclovir, or less frequently foscarin, is usually used for prophylaxis and preemptive treatment of CMV infection. Treatment is usually discontinued when repeated negative controls have been obtained.

**Disseminated adenovirus infection** is a life-threatening complication of HSCT recipients. Clinical manifestations include fever, hepatitis, enteritis, meningoencephalitis, and pneumonia. Young children are at particular risk of developing this complication. Diagnosis is based on the demonstration of high levels of adenovirus DNA in blood or on recovery of virus in tissue biopsies. Pharmacologic treatment of adenovirus infections is based on the use of cidofovir, which has significant renal toxicity and sometimes is unable to control viral replication. Recovery of immune system function is associated with a greater chance to survive adenovirus disseminated infection.

EBV-related **lymphoproliferative** disease (EBV-LPD) is a major complication in HSCT and solid-organ transplantation. In patients given HSCT, selective procedures of T-cell-depletion–sparing B lymphocytes, as well as the use of HLA partially matched family and unrelated donors, are risk factors for the development of EBV-LPD. These disorders usually present in the 1st 4-6 mo after transplantation as high-grade diffuse large-cell B-cell lymphomas, which are oligoclonal or monoclonal, express the full array of EBV antigens, and are of donor origin. High levels of EBV-DNA in blood and in vitro spontaneous growth of EBV-lymphoblastoid cell lines predict development of EBV-LPD.

In immunocompromised hosts, EBV-LPD originates from a deficiency of virus-specific cytotoxic T lymphocytes (CTLs), which control outgrowth of EBV-infected B cells. This finding provided the rationale for developing strategies of adoptive cell therapy to restore EBV-specific immune competence. Unselected donor leukocyte infusion, the first attempt at EBV-directed adoptive immunotherapy in humans, can induce EBV-LPD remission but exposes patients to a high risk of developing clinically relevant GVHD and is not suitable for patients transplanted from an HLA-mismatched donor. A safer approach is infusion of in vitro generated EBV-specific CTL lines of donor origin containing both CD8+ and CD4+ T lymphocytes. These CTL lines prevent lymphoproliferative disorders in patients considered at high risk, such as patients given T-cell depleted HSCT from HLA-disparate donors, and cure clinically overt LPD. Infusion of EBV-specific CTLs from third-party donors sharing HLA-class I molecules with the recipient can be also useful. In recent years, use of monoclonal antibodies directed against CD20, a molecule expressed on B cells, has significantly contributed to reduce the incidence and severity of EBV-related LPD. although it can be associated with the emergence of neoplasms in which cells are CD19+ but CD20 negative, thus rendering patients no longer susceptible to the treatment with the monoclonal antibody.
Many children given hematopoietic stem cell transplantation (HSCT) become long-term survivors. Besides chronic graft-versus-host disease (GVHD), long-term complications that may develop in pediatric transplant recipients include impaired growth, neuroendocrine dysfunction, delayed puberty, infertility, second malignancies, cataracts and other ocular complications, leukoencephalopathy, and cardiac and pulmonary dysfunction.

Children given HSCT before puberty may develop growth impairment, precluding achievement of the genetic target for adult height. The decrease in growth velocity is similar for boys and girls and is more frequently observed in patients given total-body irradiation (TBI) as part of the preparative regimen. Fractionation of irradiation has a less-adverse impact on height than does single-dose TBI, whereas the use of craniospinal radiotherapy before transplantation plays a synergistic detrimental role with TBI in favoring growth impairment. A study of 175 children younger than 6 yr of age, 6-12 yr of age, or 12-15 yr of age receiving TBI-based regimens and not treated with growth hormone reported a mean final adult height of 3.49, 1.92, and 0.37 SD below average, respectively. Chronic GVHD and its treatment with corticosteroids may also contribute to growth impairment. Serial studies of children given a busulfan-based preparative regimen indicate busulfan...
has much less impact on growth but produces the same gonadal failure as TBI-based regimens. Preparative regimens using only cyclophosphamide for children transplanted for aplastic anemia have little, if any, detrimental effect on growth and development.

Growth impairment of patients given TBI is mainly a result of direct damage of cartilage plates and to the effect of TBI on the hypothalamic–pituitary axis, which leads to an inappropriately low production of growth hormone (GH). GH deficiency is susceptible to at least partial correction through administration of hormonal replacement therapy. Annual growth evaluation should be performed in all children after HSCT. Children showing a decreased growth velocity should be further investigated through evaluation of bone age and secretion of GH in response to pharmacologic stimulus. Current studies are aimed at identifying children with GH deficiencies at an earlier age and administering hormonal replacement therapy. Initial concerns about potential risks of favoring disease recurrence or promoting development of second malignancies in GH substitute therapy have not been confirmed and GH replacement therapy is widely employed.

The use of TBI during the preparative regimen involves the thyroid gland in the irradiation field and may result in hypothyroidism. Some children who have received single-dose TBI develop either compensated (28-56%) or overt (9-13%) hypothyroidism. The use of fractionated TBI reduces the incidence of both compensated (10-14%) and overt (<5%) hypothyroidism. Children younger than 7 yr old at the time of allograft are at greater risk of developing hypothyroidism. Chemotherapy-only preparative regimens have far fewer adverse effects on normal thyroid function. The site of injury by irradiation is at the level of the thyroid gland rather than at the pituitary or hypothalamus. Therapy with thyroxine is very effective for overt hypothyroidism, but treatment of compensated hypothyroidism is more controversial, although there is evidence that hormonal replacement therapy may reduce the risk of thyroid carcinoma through a suppression of thyroid-stimulating hormone. Despite treatment of hypothyroidism, the incidence of thyroid carcinoma is not negligible. An annual echo of the thyroid gland is indicated for timely identification of nodules in the thyroid gland suspected to be of neoplastic origin. When a nodule with echo characteristics suggestive for a carcinoma is identified, a needle biopsy is indicated to clarify the histologic nature of the nodule. The cumulative incidence of hypothyroidism increases over time, underscoring the importance of annual thyroid function studies.

Gonadal hormones are essential for normal pubertal growth, as well as for development of secondary sexual characteristics. A significant proportion of patients receiving TBI-containing preparative regimens show delayed development of secondary sexual characteristics, resulting from primary ovarian or testicular failure. Laboratory evaluation of these patients reveals elevated follicle-stimulating hormone and luteinizing hormone levels with depressed estradiol and testosterone serum levels. These patients benefit from careful follow-up with evaluation of annual Tanner scores and endocrine function. Supplementation of gonadal hormones is useful for primary gonadal failure and is administered with GH to promote pubertal growth. The incidence of sex hormone deficiency is lower in patients given a busulfan-based regimen, while infertility during adulthood is a common problem of these children, as well as of those prepared to the allograft with TBI. The use of reduced-intensity regimens can have the advantage of sparing fertility in a large proportion of patients.

The overall risk of developing a secondary form of cancer is significantly higher after HSCT than in the general population. Although few studies have specifically analyzed pediatric patients, available evidence indicates that the cumulative incidence of second malignancies shows a slight, but continuous, tendency to increase over time. Several types of secondary tumors have been identified in patients given HSCT. The most frequently diagnosed neoplasms are thyroid carcinoma, brain tumors, and epithelial cancers. Young age, male gender, use of TBI during the preparative regimen, chronic GVHD, and an intrinsic genetic predisposition to develop cancer (Fanconi anemia) have been reported to be risk factors for development of secondary malignancies after HSCT.

Cataracts mainly occur in children given a radiotherapy-based preparative regimen. The incidence of cataracts is particularly high if TBI is delivered as a single-fraction (800-1,000 cGy). The introduction of fractionated TBI has led to a marked reduction of this complication to ≈10-20% of patients, one-third of whom require surgical intervention. Corticosteroids, frequently employed for treating GVHD, also promote development of cataracts. A dry eye syndrome, or keratoconjunctivitis sicca, may also affect HSCT recipients. It is often related to chronic GVHD and postradiotherapy fibrosis of the lacrimal gland and is treated with artificial tears and lubricants.

Bibliography

Allergic or atopic patients have an altered state of reactivity to common environmental and food antigens that do not cause clinical reactions in unaffected people. Patients with clinical allergy usually produce immunoglobulin (Ig) E antibodies to the antigens that trigger their illness. The term allergy represents the clinical expression of IgE-mediated allergic diseases that have a familial predisposition and that manifest as hyperresponsiveness in target organs such as the lung, skin, gastrointestinal tract, and nose. There has been a significant increase in the prevalence of allergic diseases during the last few decades. This increase is attributed to changes in environmental factors (exposure to tobacco smoke, air pollution, indoor and outdoor allergens, respiratory viruses, obesity and perhaps a decline in certain infectious diseases [hygiene hypothesis]).

KEY ELEMENTS OF ALLERGIC DISEASES

Allergens

Allergens are almost always proteins, but not all proteins are allergens. For a protein antigen to display allergenic activity, it must induce IgE production, which must lead to a type 1 hypersensitivity response upon subsequent exposure to the same protein. Biochemical properties of the allergen, stimulating factors of the innate immune response around the allergen substances at the time of exposure, stability of the allergen in the tissues, digestive system, skin, or mucosa, and the dose and time of stay in lymphatic organs during the interaction with the immune system are all factors that may cause an antigen to become an allergen. This is distinguished from general antigen responses, which induce a state of immune responsiveness without associated IgE production.

Most allergens are proteins of 10-70 kDa molecular weight; molecules <10 kDa do not bridge adjacent IgE antibody molecules on the surfaces of mast cells or basophils; most molecules >70 kDa do not pass through mucosal surfaces, a feature needed to reach antigen-presenting cells (APCs) for stimulation of the immune system. Allergens frequently contain proteases, which promote barrier dysfunction and increase allergen penetration into host tissues. Low-molecular-weight moieties, such as drugs, can become allergens by reacting with serum proteins or cell membrane proteins to be recognized by the immune system. Carbohydrate structures can also be allergens and are most relevant with the increasing use of biologics in clinical practice; patients with cetuximab-induced anaphylaxis have IgE antibodies specific for galactose-α1-3-galactose (see Chapter 151).

T Cells

Everyone is exposed to potential allergens. Atopic individuals respond to allergen exposure with rapid expansion of T-helper type 2 (Th2) cells that secrete cytokines, such as interleukin (IL)-4, IL-5, and IL-13, favoring IgE synthesis and eosinophilia. Allergen-specific IgE antibodies associated with atopic response are detectable by serum testing or positive immediate reactions to allergen extracts on prick skin testing (see Chapter 141). The Th2 cytokines IL-4 and IL-13 play a key role in immunoglobulin isotype switching to IgE (Fig. 140-1). IL-5 and IL-9 are important in differentiation and development of eosinophils. The combination of IL-3, IL-4, and IL-9 contributes to mast cell activation. Th2 cytokines are important effector molecules in the pathogenesis of asthma and allergic diseases; acute allergic reactions are characterized by infiltration of Th2 cells into affected tissues. In addition, IL-25, IL-33, and thymic stromal lymphopoietin (TSLP) contribute to Th2 response and eosinophilia.

A fraction of the immune response to allergen results in proliferation of T helper type 1 (Th1) cells. Th1 cells are typically involved in the eradication of intracellular organisms, such as mycobacteria, because of the ability of Th1 cytokines to activate phagocytes and promote the production of opsonizing and complement-fixing antibodies. The Th1 component of allergen-specific immune response contributes to chronicity and the effector phase in allergic disease. Activation and apoptosis of epithelial cells induced by Th1 cell-secreted interferon-γ (IFN-γ), tumor necrosis factor-α (TNF-α), and Fas ligand constitute an essential pathogenic event for the formation of eczematous lesions in atopic dermatitis and bronchial epithelial cell shedding in asthma.

Chronic lesions of allergic reactions are characterized by infiltration of Th1 and Th17 cells. This is important because Th1 cytokines such as IFN-γ can potentiate the function of allergic inflammatory effector cells such as eosinophils and thereby contribute to disease severity. Th17 and Th22 cells link the immune response to tissue inflammation; IL-17A and IL-17F and IL-22 are their respective prototype cytokines. Although both T-helper cell subsets play roles in immune defense to extracellular bacteria, IL-17 augments inflammation, whereas IL-22 plays a tissue-protective role. Cytokines in the IL-17 family act on multiple cell types, including epithelial cells and APCs, to cause the release of chemokines, antimicrobial peptides, and proinflammatory cytokines to enhance inflammation and antimicrobial responses. In addition, recently identified Th9 cells produce IL-9, but not other typical Th1, Th2, and Th17 cytokines, and constitute a distinct population of effector T cells that promotes tissue inflammation. Figure 140-2 depicts the complex cytokine cascades involving Th1, Th2, Th9, Th17 and Th22 cells.

T-regulatory (Treg) cells are a subset of T cells thought to play a critical role in expression of allergic and autoimmune diseases. These cells have the ability to suppress effector T cells of either the Th1 or Th2 phenotypes (Fig. 140-3). Treg cells express CD4+CD25+ surface molecules and immunosuppressive cytokines such as IL-10 and transforming growth factor-β (TGF-β). The forkhead box/winged-helix transcription factor gene FOXP3 is expressed specifically by CD4+CD25+ Treg cells and programs their development and function. Adoptive transfer of Treg cells inhibits the development of airway eosinophilia and protects against airway hyperreactivity in animal models of asthma. T-cell response to allergens in healthy individuals shows a wide range, from no detectable response to involvement of active peripheral tolerance mechanisms mediated by different subsets of Treg cells. Individuals who are not allergic even though they are exposed to high doses of allergens, such as beekeepers and cat owners, show a detectable allergen-specific IgG4 response accompanied by IL-10-producing Treg cells. It is thought that CD4+CD25+ Treg cells play an important role in mitigating the allergic immune response and that the lack of such cells may predispose to the development of allergic diseases. Patients with mutations in the human FOXP3 gene lack CD4+CD25+ Treg cells and develop severe immune dysregulation, with polyendocrinopathy, food allergy, and high serum IgE levels (XLAAD/
Allergy and the Immunologic Basis of Atopic Disease

IPEX disease) (see Chapter 126). In addition to Treg cells, IL-10 secr
ting and allergen-specific Breg cells that increase during allergen-
specific immunotherapy, and may play a role in allergen tolerance were
recently demonstrated.

Antigen-Presenting Cells

Dendritic cells, Langerhans cells, monocytes, and macrophages have
the ability to present allergens to T cells and thereby modulate allergic
inflammation by controlling the type of T-cell development. APCs are
a heterogeneous group of cells that share the property of antigen pre
sentation in the context of the major histocompatibility complex
(MHC) and are found primarily in lymphoid organs and the skin.
Dendritic cells (DCs) and Langerhans cells are unique in their ability
to prime naïve T cells and are responsible for the primary immune
response, or the sensitization phase of allergy. Monocytes and mac
rophages are thought to contribute to activating memory T-cell
responses upon reexposure to allergen, which characterizes the elici
tation phase of allergy.

Peripheral DCs residing in sites such as the skin, intestinal lamina
propria, and lung are relatively immature. These immature DCs take
up antigens in tissues and then migrate to the T-cell areas in locally
draining lymph nodes. The DCs undergo phenotypic and functional
changes during migration, characterized by increased expression of
MHC class I, MHC class II, and costimulatory molecules that react
with CD28 expressed on T cells. In the lymph nodes, they directly
process antigens to resting T cells to induce their prolifera

\]
(IFN-α) and also help B cells for antibody production. There is considerable interest in the role of TSLP, which is overexpressed in the mucosal surfaces and skin of atopic individuals. TSLP enhances Th2 cell differentiation by inducing expression of OX40L on immature myeloid DCs in the absence of IL-12 production.

Presence of allergen-specific IgE on the cell surfaces of APCs is a unique feature of atopy. Importantly, the formation of high-affinity IgE receptor I (FcεRI)/IgE/allergen complexes on APC cell surfaces markedly facilitates allergen uptake and presentation. The clinical importance of this phenomenon is supported by the observation that FcεRI-positive Langerhans cells bearing IgE molecules are a prerequisite for skin-applied, aeroallergen provocation of eczematous lesions in patients with atopic dermatitis. The role of the low-affinity IgE receptor II (FcεRII, CD23) on monocytes/macrophages is less clear, although it appears that under certain conditions it can also facilitate antigen capture. Cross-linking of FcεRII, as well as FcεRI, on monocytes/macrophages leads to the release of inflammatory mediators. There is a critical role for DCs in induction of oral tolerance; tolerogenic DCs are compartmentalized within the mucosa and present antigen through a mechanism designed to produce a Th1/Treg–suppressive response that ablates allergen-specific T cells.

**Immunoglobulin E and its Receptors**

The acute allergic response depends on IgE and its ability to bind selectively to the α chain of the high-affinity FcεRI or the low-affinity FcεRII (CD23). Cross-linking of receptor-bound IgE molecules by allergen initiates a complex intracellular signaling cascade followed by the release of various mediators of allergic inflammation from mast cells and basophils. The FcεRI molecule is also found on the surface of antigen-presenting DCs (e.g., Langerhans cells), but differs from the structure found on mast cells/basophils in that the FcεRI molecule found on DCs lacks the β chain. CD23 is found on B cells, eosinophils, platelets, and DCs. Cross-linking and FcεRI aggregation on mast cells and basophils can also lead to anaphylaxis (see Chapter 149). Differential expression of tyrosine kinases responsible for positive and negative regulation of mast cell/basophil degranulation are thought to be responsible for this aberrant allergic response.

The induction of IgE synthesis requires 2 major signals. The first signal (signal 1) initiates IL-4 or IL-13 activation of germline transcription at the ε Ig locus, which dictates isotype specificity. The second signal (signal 2) involves the engagement of CD40 on B cells by CD40 ligand expressed on T cells. This engagement results in activation of the recombination machinery, resulting in DNA switch recombination. Interactions between several costimulatory molecule pairs (CD28 and B7; lymphocyte function–associated antigen-1 and intercellular adhesion molecule-1; CD2 and CD58) can further amplify signal 1 and signal 2 to enhance IgE synthesis. Factors that inhibit IgE synthesis include Th1-type cytokines (IL-12, IFN-α, IFN-γ) and microbial DNA containing CpG (cytosine-phosphate-guanine) repeats.

**Eosinophils**

Allergic diseases are characterized by peripheral blood and tissue eosinophilia. Eosinophils participate in both innate and adaptive immune responses and, like mast cells, contain dense intracellular granules that are sources of inflammatory proteins. These granule proteins include major basic protein, eosinophil-derived neurotoxin, peroxidase, and cationic protein. Eosinophil granule proteins damage epithelial cells, induce airway hyperresponsiveness, and cause degranulation of basophils and mast cells. Major basic protein released from eosinophils can bind to an acidic moiety on the M2 muscarinic receptor and block its function, thereby leading to increased acetylcholine levels and the development of increased airway hyperreactivity. Eosinophils are also a rich source of prostaglandins and leukotrienes; in particular, cysteinyl leukotriene C4 contracts airway smooth muscle and increases vascular permeability. Other secretory products of eosinophils include cytokines (IL-4, IL-5, TNF-α), proteolytic enzymes, and reactive oxygen intermediates, all of which significantly enhance allergic tissue inflammation.

Several cytokines regulate the function of eosinophils in allergic disease. Eosinophils develop and mature in the bone marrow from myeloid precursor cells activated by IL-3, IL-5, and granulocyte-macrophage colony-stimulating factor (GM-CSF). Allergen exposure of allergic patients causes resident hematopoietic CD34 cells to express the IL-5 receptor. The IL-5 receptor activation induces eosinophil maturation, causing eosinophils to synthesize granule proteins, prolonging their survival, potentiating degranulation of eosinophils, and stimulating release of eosinophils from the bone marrow. GM-CSF also enhances proliferation, cell survival, cytokine production, and degranulation of eosinophils. Certain chemokines, such as RANTES (regulated upon activation, normal T-cell expressed and secreted),
macrophage inflammatory protein-1α (MIP-1α), and eotaxins, are important for recruiting eosinophils into local allergic tissue inflammatory reactions. Eotaxins mobilize IL-5-dependent eosinophil colony–forming progenitor cells from the bone marrow. These progenitors are rapidly cleared from the blood and either return to the bone marrow or are recruited to inflamed tissue sites.

**Mast Cells**

Mast cells are derived from CD34 hematopoietic progenitor cells that arise in bone marrow. Upon entering the circulation, they travel to peripheral tissue, where they undergo tissue-specific maturation. Mast cell development and survival relies on interactions between the tyrosine kinase receptor c-kit expressed on the surface of mast cells and the fibroblast-derived c-kit ligand stem cell factor. Unlike mature basophils, mature mast cells do not typically circulate in the blood. They are, instead, widely distributed throughout connective tissues, where they often lie adjacent to blood vessels and beneath epithelial surfaces that are exposed to the external environment, such as the respiratory tract, gastrointestinal tract, and skin. So placed, mast cells are positioned anatomically to participate in allergic reactions. At least 2 sub-populations of human mast cells are recognized: mast cells with tryptase and mast cells with both tryptase and chymase. Mast cells with tryptase are the predominant type found in the lung and small intestinal mucosa, whereas mast cells with both tryptase and chymase are the predominant type found in skin, the gastrointestinal submucosa, and blood vessels.

Mast cells contain, or produce on appropriate stimulation, a diverse array of mediators that have different effects on allergic inflammation and organ function. They include preformed granule-associated mediators (histamine, serine proteases, proteoglycans) and membrane-derived lipid, cytokine, and chemokine mediators arising from de novo synthesis and release. The most important mast cell-derived lipid mediators are the cyclooxygenase and lipoxygenase metabolites of arachidonic acid, which have potent inflammatory activities. The major cyclooxygenase product of mast cells is prostaglandin D₃, and the major lipoxygenase products are the sulfidopeptidoleukotrienes (LTs): LTC₄ and its peptidolytic derivatives LTD₄ and LTE₄. Mast cells also can produce cytokines that promote Th2-type responses (IL-4, IL-13, GM-CSF) and inflammation (TNF-α, IL-6), and regulate tissue remodeling (TGF; vascular endothelial cell growth factor). Immunologic activation of mast cells and basophils typically begins with cross-linkage of IgE bound to the FcεRI with multivalent allergen. Mast cell surface FcεRI is increased by IL-4 and IgE. Surface levels of FcεRI decrease in subjects receiving treatment with anti-IgE antibody that lowers serum IgE, which is of potential therapeutic interest.

**MECHANISMS OF ALLERGIC TISSUE INFLAMMATION**

IgE-mediated immune responses can be classified chronologically according to 3 reaction patterns. The *early-phase response* is the immediate response after allergen is introduced into target organs. This response is characterized by mast cell degranulation and release of preformed mediators, occurring within an immediate time frame of between 1 and 30 min after allergen exposure and resolving within 1-3 hr. Acute reactions are associated with increased local vascular permeability, which leads to leakage of plasma proteins, tissue swelling, and increased blood flow, as well as itching, sneezing, wheezing, and acute abdominal cramps in the skin, nose, lung, and gastrointestinal tract, respectively, depending on the targeted organ.

A second, *late-phase response* can occur within hours of allergen exposure, reaching a maximum at 6-12 hr and resolving by 24 hr. Late-phase responses are characterized in the skin by edema, redness, and induration; in the nose by sustained nasal blockage; and in the lung by airway obstruction and persistent wheezing. In general, late-phase responses are associated with early infiltration of neutrophils and eosinophils followed by basophils, monocytes, macrophages, and Th2-type cells. Recruitment of inflammatory cells from the circulation requires increased expression of adhesion molecules on their cell surfaces and expression of their ligand on endothelial cells, which are under the control of cytokines. Several hours after allergen exposure, TNF-α released by activated mast cells induces the vascular endothelial expression of cell adhesion molecules, and this change leads to transendothelial migration of various inflammatory cells. Preferential accumulation of eosinophils occurs through interactions between selective adhesion molecules on the eosinophil cell surface (e.g., α4β1, integrin or very late antigen-4); vascular cell adhesion molecule-1 surface expression can be enhanced by IL-4 and IL-13 on endothelial cells.

Chemokines are chemotactic cytokines that play a central role in tissue-directed migration of inflammatory cells. RANTES, MIP-1α, monocyte chemotactic protein (MCP)-3, and MCP-4 are chemotactic attractants for eosinophils and mononuclear cells, whereas eotaxins are relatively selective for eosinophils. These chemotactic factors have been detected in epithelium, macrophages, lymphocytes, and eosinophils at sites of late-phase responses and allergic tissue inflammation. Blockade of these chemokines leads to significant reduction in tissue-directed migration of allergic effector cells.

In the third reaction pattern, *chronic allergic disease*, tissue inflammation can persist for days to years. Several factors contribute to persistent tissue inflammation, including recurrent exposure to allergens and microbial agents. The repeated stimulation of allergic effector cells such as mast cells, basophils, eosinophils, and Th2 cells contributes to unresolved inflammatory conditions. Additionally, Th2-type cytokines (IL-3, IL-5, GM-CSF) secreted during allergic reactions can prolong survival of allergic effector cells by delaying apoptosis. Local differentiation of tissue-infiltrating eosinophil precursors induced by IL-5 results in self-generation of eosinophils, further sustaining damage of local tissue. Tissue remodeling leading to irreversible changes in target organs is also a feature of chronic allergic disease. In asthma, remodeling involves thickening of the airway walls and submucosal tissue, as well as smooth muscle hypertrophy and hyperplasia, which are associated with a decline in lung function. This is an unexpected role for eosinophils in airway remodeling as well as chronic inflammation. In atopic dermatitis, lichenification is an obvious manifestation of skin remodeling.

Th2 cytokines can not only maintain allergic inflammation but also influence tissue remodeling by activating resident cells in target organs; IL-4, IL-9, and IL-13 induce mucus hypersecretion and metaplasia of mucus cells; IL-4 and IL-13 stimulate fibroblasts and angiogenesis. IL-11 expressed by eosinophils and epithelial fibrosis. TGF-β produced by eosinophils and fibroblasts can enhance subepithelial fibrosis. IL-11 expressed by eosinophils and epithelial cells also contributes to subepithelial fibrosis, in addition to enhancing deposition of collagen and the accumulation of fibroblasts. Additional interleukins released from epithelial cells and DCs, such as IL-25, IL-31, and IL-33, also contribute to the Th2- and eosinophilic inflammation in the affected tissues. The resulting tissue injury amplifies further epithelial injury through proinflammatory cytokine release, extracellular matrix deposition in target organs, and angiogenesis. Genetic predisposition to aberrant injury-repair responses may contribute to chronicity of illness. Once the allergic immune response is established, it can be self-perpetuating and can lead to chronic disease in genetically predisposed individuals. The subsequent infiltration of Th1 cells and Th17 cells enhances the inflammatory potential of allergic effector cells and contributes to chronic tissue inflammatory responses through the release of proinflammatory cytokines and chemokines. In addition, an autoimmune response might be playing a causative role in allergic inflammation resulting from possible mechanisms through IgE autoantibodies, IgG autoantibodies, and Th1 cell and Th17 cell autoactivity.

**GENETIC BASIS OF ATOPY**

Allergic diseases are complex genetic conditions susceptible to environmental triggers. Several major groups of genes are associated with allergic diseases: genes that regulate systemic expression of atopy (increased IgE synthesis, eosinophilia, mast cell responses) that are commonly expressed among various allergic diseases, genes that control barrier function in specific target organs (e.g., the skin in atopic
dermatitis, the lung in asthma, the gastrointestinal tract in food allergy), and genes encoding pattern-recognition receptors of the innate immune system that engage microbial pathogens and influence adaptive immune responses. Once allergic responses have been initiated, a genetic predisposition to chronic allergic inflammation and aberrant injury-repair responses contribute to tissue remodeling and persistent disease.

Atopic diseases have a strong familial predisposition, with approximately 60% heritability found in twin studies of asthma and atopic dermatitis. The 5q23-35 region comprises several genes implicated in allergic disease pathogenesis, including genes coding for Th2 cytokines (IL-3, IL-4, IL-5, IL-9, IL-13, GM-CSF). Among these, IL4 is a well-studied potential candidate gene. A nucleotide change at position 589 of the IL4 promoter region is associated with the formation of a unique binding site for NF-AT (nuclear factor for activated T cells) transcription factor, increased IL-4 gene transcription, higher NF-AT binding affinity, and increased IgE production. Similarly, IL13 coding region variants have been associated with asthma and atopic dermatitis. An association between atopy and a gain-of-function polymorphism on chromosome 16, which codes for the α subunit of the IL-4R, has been found. This finding is consistent with the important role of IL-4, IL-13, and their receptors in the immunopathogenesis of allergic diseases.

Genome-wide searches have also linked atopy to chromosome region 11q13. The gene encoding the β subunit of FcεRI-β has been proposed to be the candidate gene in this region. The β subunit gene modifies the FcεRI activity on mast cells, and several genetic variants of FcεRI-β are associated with asthma and atopic dermatitis. Chromosome 6 contains genes coding for human leukocyte antigen class I and class II molecules, which regulate the specificity and intensity of the immune responses to specific allergens. IgE responses to specific allergens, such as ragweed antigen Amb a V and mite allergens Der p I, have been linked to specific MHC class II loci. TNF-α, a key cytokine that contributes to the influx of inflammatory cells, is also located on chromosome 6. TNF-α polymorphisms are associated with asthma.

Barrier dysfunction has a key role in the pathogenesis of allergic diseases. Genetic linkage studies of atopic dermatitis have demonstrated the importance of chromosome 1q21, which contains a cluster of genes involved in epidermal differentiation. Filaggrin is a protein that is essential in the formation of the stratum corneum. Null mutations of the filaggrin gene are strongly associated with early onset and severe atopic dermatitis. Mutations in the gene encoding the serine protease inhibitor SPINK5 have been shown to cause Netherton disease, a single-gene disorder associated with erythroderma, food allergy, and high serum IgE levels. A common polymorphism in SPINK5 (in particular, Glu420Lys) increases the risk of developing atopic dermatitis and asthma. SPINK5 is expressed in the outer epidermis and is thought to be critical in neutralizing the proteolytic activity of Staphylococcus aureus and common allergens such as Der p 1, which use these proteases to penetrate the skin to induce allergic responses. Barrier dysfunction is involved in other allergic diseases, such as asthma and rhinosinusitis, but likely involves other barrier genes, such as those encoding gap junctions.

Candidate genes associated with asthma susceptibility have been identified by positional cloning: GPRA (G-protein coupled receptor for asthma susceptibility on chromosome 7p14), ADAM-33 (a disintegrin and metalloproteinase 33 on chromosome 20p), and DPP10 (dipeptidyl peptidase 10 on chromosome 2q14). The functions of these genes do not fit into classical pathways of atopy and therefore provide new insights into asthma pathogenesis. GPRA encodes a G-protein coupled receptor, with isoforms expressed in bronchial epithelial cells and smooth muscle in asthmatic persons, suggesting an important role for these tissues in asthma. ADAM-33 is expressed in bronchial smooth muscle and has been linked to bronchial hyperresponsiveness. DPP10 encodes a dipeptidyl dipeptidase that can remove the terminal 2 peptides from certain proinflammatory chemokines, a change that may modulate allergic inflammation.

Pattern-recognition receptors of the innate immune system, which are expressed by epithelial cells and DCs, are associated with disease susceptibility. These receptors recognize specific microbial compo-

Chapter 141
Diagnosis of Allergic Disease
Jennifer S. Kim, Supinda Bunyavanich, and Scott H. Sicherer

ALLERGY HISTORY
Obtaining a complete history from the allergic patient involves eliciting a description of all symptoms along with their timing and duration, exposure to common allergens, and responses to previous therapies. Because patients often suffer from more than 1 allergic disease, the presence or absence of other allergic diseases, including allergic rhinoconjunctivitis, asthma, food allergy, eosinophilic esophagitis, atopic dermatitis, and drug allergy should be determined. A family history of allergic disease is common and is one of the most important factors predisposing a child to the development of allergies. The risk of allergic disease in a child approaches 50% when 1 parent is allergic and 66% when both parents are allergic, with maternal history of atopy having a greater effect than paternal history.

Several characteristic behaviors are often seen in allergic children. Because of nasal pruritus and rhinorrhea, children with allergic rhinitis often perform the allergic salute by rubbing their nose upward with the palm of their hand. This repeated maneuver may give rise to the nasal crease, a horizontal wrinkle over the bridge of the nose. Characteristic vigorous grinding of the eyes with the thumb and side of the fist is frequently observed in children with allergic conjunctivitis. The allergic cluck is produced when the tongue is placed against the roof of the mouth to form a seal and withdrawn rapidly in an effort to scratch the palate. The presence of other symptoms, such as fever, unilateral nasal obstruction, and purulent nasal discharge, suggests other diagnoses.

The timing of onset and the progression of symptoms are relevant. The onset of recurrent or persistent nasal symptoms coinciding with placement in a daycare center might suggest recurrent infection rather than allergy. When patients present with a history of episodic acute symptoms, it is important to review the setting in which symptoms occur as well as the activities and exposures that immediately precede their onset. Symptoms associated with lawn mowing suggest allergy to grass pollen or fungi, whereas if symptoms occur in homes with pets, animal dander sensitivity is an obvious consideration. Reproducible reactions after ingestion of a specific food raise the possibility of food allergy. When symptoms wax and wane but evolve gradually and are more chronic in duration, a closer look at whether the timing and progression of symptoms correlate with exposure to a seasonal aeroallergen is warranted.

Aeroallergens, such as pollens and fungal spores, the concentrations of which in outdoor air fluctuate seasonally, are prominent causes of allergic disease. Correlating symptoms with seasonal pollination patterns of geographically relevant plants and trees along with information provided by local pollen counts can aid in identifying the allergen. Throughout most of the United States, trees pollinate in the early spring, grasses pollinate in the late spring and early summer, and
weeds pollinate in late summer through the fall. The presence of fungal spores in the atmosphere follows a seasonal pattern in the northern United States with spore counts rising with the onset of warmer weather and peaking in late summer months, only to recede again with the first frost through the winter. In warmer regions of the southern United States, fungal spores and grass pollens may cause symptoms on a perennial basis.

Rather than experiencing seasonal symptoms, some patients suffer allergic symptoms year-round. In these patients, sensitization to perennial allergens usually found indoors, such as dust mites, animal dander, cockroaches, and fungi, warrants consideration. Species of certain fungi, such as Aspergillus and Penicillium, are found indoors whereas Alternaria is found in both indoor and outdoor environments. Cockroach allergens are often problematic in inner city environments. Patients sensitive to perennial allergens often also become sensitized to seasonal allergens and experience baseline symptoms year-round with worsening during the pollen seasons.

The age of the patient is an important consideration in identifying potential allergens. Infants and young children are first sensitized to allergens that are in their environment on a continuous basis, such as dust mites, animal dander, and fungi. Sensitization to seasonal allergens usually takes several seasons of exposure to develop and is thus unlikely to be a significant trigger of symptoms in infants and toddlers.

Food allergies are more common in infants and young children, resulting primarily in cutaneous, gastrointestinal, and, less frequently, respiratory symptoms. Symptoms of immediate or immunoglobulin (Ig) E-mediated hypersensitivity food reactions develop within minutes to 2 hr after ingestion of the offending food. Symptoms of non–IgE-mediated food allergies are often delayed or chronic (see Chapter 151).

Complete information from previous evaluations and prior treatments for allergic disease should be reviewed, including impact of changes in local environment (e.g., home vs. school), response to medications, elimination diets, and duration and impact of allergen immunotherapy (if applicable). Improvement in symptoms with medications or avoidance strategies used to treat allergic disease provides additional evidence for an allergic process.

A thorough environmental survey should be performed, focusing on potential sources of allergen and/or irritant exposure, particularly when respiratory symptoms (upper and/or lower) are reported. The age and type of the dwelling, how it is heated and cooled, the use of humidifiers or air filtration units, and any history of water damage should be noted. Forced air heating may stir up dust mite, fungi, and animal allergens. The irritant effects of wood-burning stoves, fireplaces, and kerosene heaters may provoke respiratory symptoms. Increased humidity or water damage in the home is often associated with greater exposure to dust mites and fungi. Carpeting serves as a reservoir for dust mites, fungi, and animal dander. The number of domestic pets and their movements about the house should be ascertained. Special attention should be focused on the bedroom, where a child spends a significant proportion of time. The age and type of bedding, the number of stuffed animals, type of window treatments, and the accessibility of pets to the room should be reviewed. The number of smokers in the home and where they smoke is useful information. Activities that might result in exposure to allergens or respiratory irritants such as paint fumes, cleansers, sawdust, or glues should be identified. Similar information should be obtained in regard to other environments where the child spends large portions of time, such as a relative’s home or school setting.

**PHYSICAL EXAMINATION**

In patients with asthma, spirometry should be performed. If respiratory distress is observed, pulse oximetry should be performed. The child presenting with a chief complaint of rhinitis or rhinoconjunctivitis should be observed for mouth breathing, paroxysms of sneezing, sniffing/snorting, throat clearing, and rubbing of the nose and eyes (representing pruritus). Infants should be observed during feeding for nasal obstruction severe enough to interfere with feeding or for more obvious signs of aspiration or gastroesophageal reflux. The frequency and nature of coughing that occurs during the interview and any positional increase in coughing or wheezing should be noted. Children with asthma should be observed for congested or wet cough, tachypnea at rest, retractions, and audible wheezes, which may worsen with crying. Patients with atopic dermatitis should be monitored for repetitive scratching and the extent of skin involvement.

Because children with severe asthma as well as those receiving chronic or frequent oral corticosteroids may suffer growth suppression, an accurate height should be plotted at regular intervals. However, long-term follow-up studies suggest that use of inhaled glucocorticoids in prepubertal children is associated with a small initial decrease in attained height (~1 cm) that may persist as a reduction in adult height that is not progressive or cumulative. Poor weight gain in a child with chronic chest symptoms should prompt consideration of cystic fibrosis. Anthropometric measures are also important to monitor in those on restricted diets because of multiple food allergies or eosinophilic esophagitis. Blood pressure should be measured to evaluate for steroid-induced hypertension. The patient with acute asthma may present with pulsum paradoxum, defined as a drop in systolic blood pressure during inspiration >10 mm Hg. Moderate to severe airways obstruction is indicated by a decrease of >20 mm Hg. An increased heart rate may be the result of an asthma flare or the use of a β-agonist or decongestant. Fever is not caused by allergy alone and should prompt consideration of an infectious process, which may exacerbate asthma.

Parents are often concerned about blue-gray to purple discolorations beneath their child’s lower eyelids, which can be attributed to venous stasis and are referred to as allergic shiners. They are found in up to 60% of allergic patients and almost 40% of patients without allergic disease. Thus, “shiners” may suggest, but are not diagnostic of, allergic disease. In contrast, the Dennie-Morgan folds (Dennie lines) are a feature of atopic dermatitis. These are prominent infraorbital skin folds that extend in an arc from the inner canthus beneath and parallel to the lower lid margin.

In patients with allergic conjunctivitis, involvement of the eyes is bilateral. Examination of the conjunctiva reveals varying degrees of lacrimation, conjunctival injection, and edema. In severe cases, periorbital edema involving primarily the lower eyelids or chemosis (conjunctival edema that is gelatinous in appearance) may be observed. The classic discharge associated with allergic conjunctivitis is usually described as “stringy” or “ropy.” In children with vernal conjunctivitis, a more severe, chronic phenotype, examination of the tarsal conjunctiva may reveal cobblestoning. Keratocononus, or protrusion of the cornea, may occur in patients with vernal conjunctivitis or periorbital atopic dermatitis as a result of repeated trauma produced by persistent rubbing of the eyes. Children treated with high-dose or chronic corticosteroids are at risk for development of posterior subcapsular cataracts.

The external ear should be examined for eczematous changes in patients with atopic dermatitis, including the postauricular area and base of the earlobe. Because otitis media with effusion is common in children with allergic rhinitis, pneumatic otoscopy should be performed to evaluate for the presence of fluid in the middle ear and to exclude infection.

Examination of the nose in allergic patients may reveal the presence of a nasal crease. Nasal patency should be assessed, and the nose examined for structural abnormalities affecting nasal airflow, such as septal deviation, turbinate hypertrophy, and nasal polyps. Decrease or absence of the sense of smell should raise concern about chronic sinusitis or nasal polyps. Nasal polypos in children should raise concerns of cystic fibrosis. The nasal mucosa in allergic rhinitis is classically described as pale to purple in comparison to the beefy red mucosa of patients with nonallergic rhinitis. Allergic nasal secretions are typically thin and clear. Purulent secretions suggest another cause of rhinitis. The frontal and maxillary sinuses should be palpated to identify tenderness to pressure that might be associated with acute sinusitis.

Examination of the lips may reveal cheilitis caused by drying of the lips from continuous mouth breathing or repeated licking of the lips in an attempt to replenish moisture and relieve discomfort (lip licker’s dermatitis). Tonsillar and adenoidal hypertrophy along with a history of impressive snoring raises the possibility of obstructive
sleep apnea. The posterior pharynx should be examined for the pres- sence of postnasal drip and posterior pharyngeal lymphoid hyperplasia ("cobblestoning").

Chest findings in asthmatic children vary significantly and may depend on disease duration, severity, and activity. In a child with well-controlled asthma, the chest should appear entirely normal on examination between asthma exacerbations. Examination of the same child during an acute episode of asthma may reveal hyperinflation, tachypnea, use of accessory muscles, wheezing, and decreased air exchange with a prolonged expiratory time. Tachycardia may be caused by the asthma exacerbation or accompanied by jitteriness after treatment with β-agonists. Decreased airflow or rhonchi and wheezes over the right chest may be noted in children with mucus plugging and right middle lobe atelectasis. The presence of cyanosis indicates severe respiratory compromise. Unilateral wheezing after an episode of coughing and choking in a small child without a history of previous respiratory illness suggests aspiration of a foreign body. Wheezing limited to the larynx in association with inspiratory stridor may be seen in older children and adolescents with vocal cord dysfunction. Digital clubbing is rarely seen in patients with uncomplicated asthma and should prompt further evaluation to rule out other potential chronic diagnoses, such as cystic fibrosis.

The skin of the allergic patient should be examined for evidence of urticaria/angioedema or atopic dermatitis. Xerosis, or dry skin, is the most common skin abnormality of allergic children. Keratosis pilaris, often found on facial cheeks and extensor surfaces of the upper arms and thighs, is a benign condition characterized by skin-colored or slightly pink papules caused by keratin plugs lodged in the openings of hair follicles. Examination of the skin of the palms and soles may reveal thickened skin and exaggerated palmar and plantar creases (hyperlinearity) in children with moderate-to-severe atopic dermatitis.

### Diagnostic Testing

#### In Vitro Tests

Allergic diseases are often associated with increased numbers of eosinophils circulating in the peripheral blood and invading the tissues and secretions of target organs. Eosinophilia, defined as the presence of >500 eosinophils/µL in peripheral blood, is the most common hematologic abnormality of allergic patients. Seasonal increases in the number of circulating eosinophils may be observed in sensitized patients after exposure to allergens such as tree, grass, and weed pollens. The number of circulating eosinophils can be suppressed by certain infections and systemic corticosteroids. In certain pathologic conditions, such as drug reactions, eosinophilic pneumonias, and eosinophilic esophagitis, significantly increased numbers of eosinophils may be present in the target organ in the absence of peripheral blood eosinophilia. Increased numbers of eosinophils are observed in a wide variety of disorders in addition to allergy (Table 141-1; see Chapter 129). Eosinophil counts >1500 without an identifiable etiology should suggest 1 of the 2 hyper eosinophilic syndromes (Table 141-1; see Chapter 129).

Nasal and bronchial secretions may be examined for the presence of eosinophils. The presence of eosinophils in the sputum of asthmatic patients is classic. An increased number of eosinophils in a smear of nasal mucus with Hansel stain is a more sensitive indicator of nasal allergies than peripheral blood eosinophilia and can aid in distinguishing allergic rhinitis from other causes of rhinitis. An elevated IgE value is often found in the serum of allergic patients, because IgE is the isotype to 2.4 µg/mL in peripheral blood, is the most common hematologic abnormality of allergic children. Keratosis pilaris, often found on facial cheeks and extensor surfaces of the upper arms and thighs, is a benign condition characterized by skin-colored or slightly pink papules caused by keratin plugs lodged in the openings of hair follicles. Examination of the skin of the palms and soles may reveal thickened skin and exaggerated palmar and plantar creases (hyperlinearity) in children with moderate-to-severe atopic dermatitis.

**FIP1L1-PDGFRα, FIP1-like 1–platelet-derived growth factor receptor α.**
that the diagnostic value of a total IgE level is poor. Approximately one-half of patients with allergic disease have total IgE levels in the normal range. However, measurement of total IgE is indicated when the diagnosis of allergic bronchopulmonary aspergillosis is suspected because total serum IgE concentration >1,000 ng/mL is a criterion for diagnosis of this disorder (see Chapter 237.1). Total serum IgE may also be elevated in several nonallergic diseases (Table 141-2; see Chapter 126).

The presence of IgE specific for a particular allergen can be documented in vivo by skin testing or in vitro by the measurement of allergen-specific IgE (sIgE) levels in the serum (Table 141-3). The first test for documenting the presence of sIgE was called the radioallergosorbent test because it used a radiolabeled anti-IgE antibody. The radioallergosorbent test has been replaced by an improved generation of automated enzymatic sIgE immunoassays. These assays use solid-phase supports to which allergens of an individual allergen extract are bound. A small amount of the patient’s serum is incubated with the allergen-coated support. The allergen-coated support bound to the patient’s sIgE is then incubated with enzyme-conjugated antihuman IgE. Incubation of this sIgE-antihuman IgE complex with a fluorescent substrate of the conjugated enzyme results in the generation of fluorescence that is proportional to the amount of sIgE in the serum sample. The amount of sIgE in the serum sample is calculated by interpolation from a standard calibration curve and reported in arbitrary mass units (kilo-IU of allergen-specific antibody per unit volume of sample [kU/L]). Laboratory reports may specify classes, counts, or units, but quantification of results in kU/L is most useful. There are 3 commercial detection systems approved by the U.S. Food and Drug Administration that have excellent performance characteristics, but the individual systems do not measure sIgE antibodies with comparable efficiencies and thus are not interchangeable. Component testing refers to emerging diagnostic tests where sIgE is measured to specific proteins that comprise allergens (e.g., Ara h 2 from peanut or Bet v 1 from birch pollen), rather than to a mixture of the allergens extracted from the source. Testing sIgE to component allergens may add additional diagnostic value by differentiating immune responses that are directed toward clinically relevant allergenic proteins.

*Skin testing may be the prick test or intradermal (ID) injection.*
(SPT) result is negative but the history suggestive, selective skin testing (for vaccines, venom, drugs, and aeroallergens) using the intradermal technique may be performed. This technique involves using a 26-gauge needle to inject 0.01-0.02 mL of an allergen extract diluted 1,000- to 100-fold into the dermis of the arm. Intradermal skin tests are not recommended for use with food allergens because of the risk of triggering anaphylaxis. Irritant rather than allergic reactions can occur with intradermal skin testing if higher concentrations of extracts are used. Although skin prick testing is less sensitive than intradermal skin testing, positive SPT results tend to correlate better with clinical symptoms.

The number of skin tests performed should be individualized, with the allergens suggested by the history taken into account. A positive and negative control SPT, using histamine and saline, respectively, is performed with each set of skin tests. A negative control is necessary to assess for dermatographism, in which reactions are caused merely by applying pressure to overly sensitive skin. A positive control is necessary to establish the presence of a cutaneous response to histamine. Medications with antihistaminic properties in addition to adrenergic agents such as ephedrine and epinephrine suppress skin test responses and should be avoided for appropriate intervals (≈5 half-lives) prior to skin testing. Prolonged courses of systemic corticosteroids may suppress cutaneous reactivity by decreasing the number of tissue mast cells as well as their ability to release mediators.

Whether identified via serologic or skin testing, detection of sIgE denotes a sensitized state (i.e., atopy or a tendency toward development of allergic disease) but is not equivalent to a clinically relevant allergic diagnosis. Many children with positive tests have no clinical symptoms upon exposure to the allergen. Increasingly strong tests (higher serum sIgE results or larger SPT wheal sizes) generally correlate with increasing likelihood of clinical reactivity (but not severity). The limitations of these test modalities underscore the need for the clinician to obtain a detailed medical history that can guide the selection and interpretation of test results. Large panels of indiscriminately performed screening tests may, therefore, provide misleading information.

Both serum sIgE tests and SPT are sensitive and have similar diagnostic properties. The benefits of the serologic immunoassays are that performance is not limited by presence of skin disease (i.e., active atopic dermatitis) or medication use (i.e., antihistamines). Advantages of skin testing are that they provide rapid results to the patient/family during the clinic visit, do not require venipuncture, and are less costly.

Under certain circumstances, provocation testing is performed to examine the association between allergen exposure and the development of symptoms. The bronchial provocation test most frequently performed clinically is the methacholine challenge, which causes potent bronchoconstriction of asthmatic but not of normal airways. Methacholine challenge testing is performed to document the presence and degree of bronchial hyperreactivity in a patient in whom asthma is suspected. After baseline spirometry values are obtained, increasing concentrations of nebulized methacholine are inhaled until a drop occurs in lung function, specifically a 20% decrease in FEV₁ (forced expiratory volume in the first second of expiration), or the patient is able to tolerate the inhalation of a set concentration of methacholine, typically 25 mg/mL.

Oral food challenges are performed to determine whether a specific food causes symptoms or whether a suspected food can be added to the diet. Food challenges are performed for those foods incriminated by the history and results of skin tests and/or immunoassays for sIgE. These challenges may be performed in an open, single-blind, double-blind, or double-blind placebo-controlled fashion and involve the ingestion of gradually increasing amounts of the suspected food at set time intervals until the patient either experiences a reaction or tolerates a normal portion (i.e., 1 serving size) of the food openly. Because of the potential for significant allergic reactions, these challenges should be performed only in an appropriately equipped facility with personnel experienced in the performance of food challenges and the treatment of anaphylaxis, including cardiopulmonary resuscitation.

Upper gastrointestinal endoscopy is required to confirm the diagnosis of eosinophilic esophagitis. One or more biopsy specimens from the proximal and distal esophagus must show eosinophil-predominant inflammation. With few exceptions, 15 eosinophils/hpf (high power field) (peak value) is considered a minimum threshold for the diagnosis.

Bibliography is available at Expert Consult.
Bibliography
The basic principles of the treatment of allergic disease include the avoidance of exposure to allergens and irritants that trigger symptoms and the pharmacologic management of symptoms caused by unavoidable acute and chronic allergen exposures. In selected patients, allergen immunotherapy may be considered.

**ENVIRONMENTAL CONTROL MEASURES**

Children spend the majority of their time in indoor environments, including the home. In an effort to save energy, houses and buildings have been built more tightly and with more insulation with limited air exchange. These factors have led to an increase in indoor humidity and higher concentrations of allergens and irritants. Examination of indoor environments suggests that house dust mite, cat, and cockroach allergens are the most common significant triggers of allergic disease in these settings; exposures to allergens from other pets, pests, mold, and respiratory irritants such as cigarette smoke are also a problem.

More than 30,000 species of mites have been identified, but the term *dust mites* usually refers to the pyroglyphid mites *Dermatophagoides pteronyssinus*, *Dermatophagoides farinae*, and *Euroglyphus maynei*, which are the major sources of allergen in house dust. Respiration and water vapor exchange occur through the skin of dust mites, rendering them sensitive to humidity and temperature extremes. The regular use of humidifiers promotes dust mite survival. Mites do not survive with relative humidity <50%. They feed on animal and human skin scales and other debris, which is why they exist in large numbers in mattresses and bedding, carpet, and upholstered furniture. They may also be found in flour and mixes for baked goods. Anaphylaxis has been reported following the ingestion of baked goods, such as waffles and pancakes, prepared with flour infested with dust mites (“pancake syndrome”). Dust mite fecal pellets are a major source of allergens. They consist of partially digested food combined with digestive enzymes encased in a permeable membrane, which keeps the fecal pellets intact. These fecal pellets have been likened to pollen grains, given their similarities in size (10-40 µm), the amount of allergen they contain, and their ability to release allergens rapidly on contact with moist mucous membranes. Mites can persist in imported furnishings for at least 2 yr; mite allergens have been shown to remain stable under domestic conditions for periods of at least 4 yr. Dust mite allergens become airborne during normal household activities; a vigorous disturbance, such as vacuuming without a vacuum bag, shaking a bed sheet, or a pillow fight, can launch significant amounts of dust mite allergens into the air. Once airborne, dust mite allergen particles settle out of the air relatively rapidly because of their size and weight. Nonetheless, dust mite allergen exposure likely occurs during sleep on mite-infested pillows and mattresses and during normal household activities when dust mite concentrations in the home are high. Levels of dust mite allergens as
low as 2 µg/g of house dust can lead to sensitization, whereas levels of 10 µg/g of house dust are associated with symptoms.

Appropriate environmental control measures can significantly reduce exposure to dust mite allergens (Table 142-1). Major emphasis should be placed on reducing exposure to dust mite allergens in the bedroom and living areas in which the child spends a large amount of time. Encasements impermeable to dust mite allergens should be placed on all pillows, the mattress, and the box spring. Dust should be removed from the surfaces of these covers and the bed frame by vacuuming weekly. The sheets and mattress pad should be washed weekly in hot water at a temperature of >54.4°C (130°F). Minimizing the number of items in the room that collect dust, such as books, drapes, toys, stuffed animals, and any clutter, is recommended. Major reservoirs of dust mite allergens that are often more difficult to deal with include the carpet and upholstered furniture, which should be vacuumed weekly with an efficient double-thickness-bagged vacuum cleaner. The actual benefit of applying acaricides or denaturing agents to carpets and upholstered furniture remains unclear, and the amount of effort required may be more than most families are willing to invest. If possible, carpet removal, at least in the bedroom, may prove a better choice for eliminating a large reservoir of dust mite allergen. Other measures for dust mite allergen control include maintaining the indoor relative humidity at <50% and keeping the air conditioning set at the lowest level during the warmer months.

In many countries, more than half of the households have pets, the most common of which are cats and dogs. The major sources of allergens from cats, dogs, and horses are hair, dander, and saliva, whereas the major source of allergens from rodents is urine. Studies of airborne cat allergen have shown that a significant portion is found on small particles. As much as 30% of airborne cat allergen may reside on particles <5 µm. Particles this small may not be adequately filtered by the nose and could potentially be deposited in the airways. Their small size enables these particles to remain airborne for longer periods and to be suspended repeatedly by air currents from heating and ventilation systems or just by walking across the carpet or sitting in an upholstered chair. Fel d 1, the major cat allergen, is a highly charged protein that readily sticks to a variety of surfaces, including walls, carpeting, and upholstered furniture. Owing to this adhesiveness, cat allergens bind to the cat owner’s clothing and are routinely transported to public buildings, including schools, where they have been measured in moderately high amounts. From these sites, significant amounts of cat allergen can subsequently be carried into homes without cats. Analysis of house dust from homes with cats reveals levels of Fel d 1 ranging from 8 µg to 1.5 mg/g of house dust. Levels of Fel d 1 in homes without cats vary from 0.2 to 80 µg/g of house dust. Sensitization to cat allergen is associated with levels ranging from 1 to 8 µg/g of house dust. Carpets, upholstered furniture, and bedding serve as reservoirs of cat allergens, resulting in the persistence of significant amounts in the home for months after a cat has been removed. Complete avoidance of cat allergen is virtually impossible, although significant reduction in exposure to cat allergens is achievable.

Removing the pet from the home is obviously the most effective means of reducing exposure to animal allergens, although it has been demonstrated that without other interventions, such as removing carpeting and upholstered furniture and wiping down walls, it takes 6 mo or more for the levels of cat allergen to drop to a level found in houses without a cat. As a result, cat owners who remove their pets from their homes should be informed not to expect immediate results. Unfortunately, advice to remove a pet from the home or keep it outdoors is often ignored. In contrast to dust mite allergens, cat allergen is light and remains suspended in the air for long periods. As a result, air cleaners with high-efficiency particulate air (HEPA) filters are helpful in reducing the amount of airborne cat allergen. Other suggested methods include washing the cat regularly and maintaining a cat allergen–free bedroom from which the cat is excluded and where mattress covers and air-filtering devices are used. The cat should also be restricted from other living areas where the sensitized child spends large amounts of time, such as the family room and other play areas (see Table 142-1). Regular vacuuming with a HEPA-filtered and double-thickness bag vacuum cleaner is also encouraged. Similar measures are suggested for the control of exposure to other animal allergens, although whether these measures reduce exposure to levels resulting in clinical improvement as demonstrated by decreased symptoms, improved peak flows, or decreases in bronchial hyperreactivity remains to be documented by appropriately controlled studies.

Infestation of the home by insects and other pests, such as mice and rats, is another potential source of significant indoor allergen exposure. Studies have identified exposure to cockroach allergens as a major risk factor for the development of asthma in inner-city children. Once sensitized, inner-city cockroach-sensitive asthmatic children with continued exposure to high levels of cockroach allergens in their bedrooms are at higher risk for urgent care visits and hospitalization than are inner-city asthmatic children who are not allergic to cockroaches. Recommended methods to decrease cockroach allergen exposure include reducing cockroaches’ access to the home by sealing cracks in the flooring and walls and removing sources of food and water by repairing leaky pipes, putting away food in sealed containers, and frequent cleaning (see Table 142-1). Regular extermination using baits or chemical treatment of infested areas is also advised.

Efforts to improve indoor air quality should also encompass reducing exposure to respiratory irritants. Passive exposure to environmental tobacco smoke worsens asthma and increases nasal symptoms in patients with allergic nasal disease. Smoking cessation should be repeatedly encouraged, and smoking indoors should never be permitted. The use of wood-burning stoves, fireplaces, and kerosene heaters should also be discouraged.

Although exposure to pollens and molds occurs primarily outdoors, these allergens are detectable indoors during the warmer months,
when their indoor levels often reflect their prevalence in the outdoor environment. During the winter, when the outdoor levels of other molds are lowest, the indoor molds Aspergillus and Penicillium are the most prevalent. Molds are often found in damp basements and thrive in conditions associated with increased moisture in the home, such as water leaks, flooding, and increased humidity promoted by the excessive use of humidifiers or swamp coolers. Exposure to indoor mold allergens can be reduced by maintaining the indoor relative humidity at <50%, removing contaminated carpets, and wiping down washable surfaces prone to fungal growth, such as shower stalls, shower curtains, sinks, drip trays, and garbage piles, with the use of solutions of detergent and 5% bleach (see Table 142-1). Dehumidifiers should be placed in damp basements. Standing water at any site in the home should be eliminated, and the cause addressed. Removing all items from the home that are prone to mold contamination is also encouraged. Keeping the windows and doors closed and using air conditioning to filter outdoor air can keep both indoor pollen and mold levels to a minimum during the warmer months, when outdoor levels of these allergens are at their peak. The use of window or attic fans is to be avoided. Laundry should be dried in a dryer rather than on a clothesline. Measures to avoid pollens and mold spores when out of the house include closing the windows and using the air conditioner when traveling in the car, avoiding moldy vegetation, and wearing a mask when these materials cannot be avoided. Outdoor activities during periods of high pollen counts should be kept to a minimum. Pollen travels best on warm, dry, breezy days but counts are lowest during chilly, wet periods. Someone other than the sensitized patient should mow the lawn and rake leaves. Hand washing after outdoor play is suggested to avoid transferring pollens from the hands to the eyes and nose. At the end of the day, showering and shampooing are suggested to avoid contamination of the bed with allergens.

**PHARMACOLOGIC THERAPY**

**Adrenergic Agents**

Adrenergic agents exert their effects through the stimulation of cell surface α- and β-adrenergic receptors in a variety of target tissues. In general, α-adrenergic receptor stimulation results in excitatory responses such as vasoconstriction, whereas β-adrenergic stimulation leads to inhibitory responses such as bronchodilation. The β-adrenergic receptors have been classified into α₁- and α₂-adrenergic receptors. There are 3 subtypes of α₁-adrenergic receptors and 3 subtypes of α₂-adrenergic receptors. The β-adrenergic receptors are further divided into 3 subtypes: β₁, β₂, and β₃. Each of these adrenergic receptors exhibits a distinctive tissue distribution. The physiologic response in a given tissue to the administration of an adrenergic agent depends on the specific receptor-binding characteristics of the drug as well as the numbers and distribution of the various types of adrenergic receptors in the tissue. Epinephrine remains the drug of choice for the treatment of anaphylaxis because of its combined α- and β-adrenergic effects. Epinephrine autoinjectors are prescribed for ease of administration and are available in 2 dosages: 0.15 mg for children who weigh <30 kg, and 0.30 mg for children who weigh ≥30 kg, according to manufacturer recommendations. Consider prescribing the 0.15 mg dose for children who weigh ≥25 kg to avoid under-dosing.

The α-adrenergic agents are effective in the treatment of allergic nasal disease because of their decongestant effects (see Tables 143-4 and 143-5). In the nose, stimulation of α₁-adrenergic receptors on postcapillary venules and of α₂-adrenergic receptors on precapillary arterioles leads to vasoconstriction, resulting in a reduction in nasal congestion. The oral decongestants currently in clinical use include pseudoephedrine and phenylephrine. These medications are available individually or in combination with antihistamines in liquid and tablet forms, including sustained-release preparations. Pseudoephedrine is rapidly and thoroughly absorbed, whereas phenylephrine, the less effective of the 2 drugs, is incompletely absorbed, resulting in a significantly lower bioavailability of ≈38%. Peak plasma concentrations of these drugs are reached between 30 min and 2 hr of administration, but the decongestant effect has not been directly correlated to the plasma concentration. Pseudoephedrine is excreted essentially unchanged by the kidney. The use of oral decongestants should be avoided in patients <6 yr of age and in patients with hypertension, coronary artery disease, glaucoma, or metabolic disorders, such as diabetes and hyperthyroidism. Reported adverse effects of oral decongestants include excitability, headache, nervousness, palpitations, tachycardia, arrhythmias, hypertension, nausea, vomiting, and urinary retention. Decongestants available as topical nasal sprays include phenylephrine, oxymetazoline, naphazoline, tetrahydrozoline, and xylometazoline. Given their efficacy and rapid onset of action, the potential for excessive use of topical nasal decongestants resulting in rebound nasal congestion (rhinitis medicamentosa) is high and patients should be carefully counseled to prevent dependency on the product. Thus, limiting the use of these sprays to 2-3 days is generally recommended.

Drugs that stimulate β-adrenergic receptors have been used for years in the treatment of asthma because of their potent bronchodilator effects (see Table 144-16). The subclassification of β-adrenergic receptors into β₁ and β₂ subtypes led to the development of drugs selective for the β₁-adrenergic receptor, such as albuterol, levalbuterol, and pirbuterol, that have the advantage of producing significant bronchodilation with less cardiac stimulation. The long-acting inhaled β₂-adrenergic agonists (LABAs) salmeterol and formoterol, with a 12-hr duration of action, are approved for use in children ≥4 yr of age. LABAs are not recommended for the treatment of acute asthma exacerbations because of their relatively slow onset of action. Concern about an increased risk of asthma-related adverse events is why LABAs are not recommended as monotherapy for the long-term control of persistent asthma, but are promoted as best used in conjunction with an inhaled steroid. Dry powder inhaled and metered-dose inhaler preparations combining a LABA with an inhaled corticosteroid have had significant impact on treatment of moderate persistent asthma. In addition to their bronchodilating effects, β₂-adrenergic agonists have been reported to improve mucociliary clearance, decrease microvascular permeability, inhibit cholinergic nerve transmission, and reduce mediator release in mast cells, basophils, and eosinophils. Although β₂-adrenergic agonists can be delivered orally, by inhalation, or by injection, the inhaled route is preferred because of the rapid onset of action and fewer adverse effects. Reported adverse effects of β₂-adrenergic agents include tremor, palpitations, tachycardia, arrhythmias, central nervous system stimulation, hyperglycemia, hypokalemia, hypomagnesemia, and a transient increase in hypoxia, which is attributed to an increase in perfusion to inadequately ventilated areas of the asthmatic lung.

**Anticholinergic Agents**

Anticholinergic drugs inhibit vagally mediated reflexes by antagonizing the action of acetylcholine at muscarinic receptors. Of the available anticholinergic agents, ipratropium bromide is the most commonly used. It is a quaternary amine that is poorly absorbed across mucosal surfaces and does not readily cross the blood–brain barrier. As a bronchodilator, it has a slower onset of action than short-acting inhaled β₂-agonists and takes longer to reach maximal effect, making it less effective as a rescue medication. There is increasing support, particularly in children, for combination therapy using ipratropium bromide and β₂-agonist therapy in more severe asthma exacerbations. Multiple doses of combined therapy can decrease risk of hospitalization in children by 25%. Ipratropium is available by prescription as a metered-dose inhaler delivering 17 µg/spray and as a 0.02% nebulized solution (500 µg/2.5 mL).

Ipratropium given as a nasal spray (0.03-0.06%) is effective in the reduction of rhinorrhea resulting from perennial nonallergic rhinitis, the common cold, and vasomotor rhinitis. The use of ipratropium is suboptimal in the treatment of moderate to severe allergic rhinitis because it does not alter other common allergic nasal symptoms, such as sneezing, nasal congestion, and pruritus. Nasal dryness and epistaxis are occasionally encountered with use of the nasal spray.

**Antihistamines**

The release of histamine and its effects on surrounding tissues is central to the development of symptoms classically associated with the allergic response. Histamine exerts its effects through binding with 1 of its 4
receptors, as H₁, H₂, H₃, or H₄ receptors. Histamine effects triggered through H₁-receptor binding are those most relevant to allergic inflammation, and include pain, pruritus, vasodilation, increased vascular permeability, smooth muscle contraction, mucus production, and the stimulation of parasympathetic nerve endings and reflexes. The antimuscarinic effect of some of the early H₁-type antihistamines may be explained by the reported 45% homology of the H₁-receptor with the human muscarinic receptor. The H₁-type antihistamines prevent the effects of H₁-receptor activation through reversible, competitive inhibition of histamine by binding to the H₁-receptor. Antihistamines work best in preventing rather than reversing the actions of histamine and are most effective when given at doses and dosing intervals resulting in the persistent saturation of target organ tissue histamine receptors.

The H₁-type antihistamines are traditionally divided into 6 classes on the basis of differences in their chemical structures (Tables 142-2 and 143-3). These antihistamines are further divided into first-generation antihistamines, which, because of their lipophilicity, cross the blood–brain barrier to exert effects on the central nervous system, and second-generation antihistamines, which exert minimal, if any, central nervous system effects because of their inability to cross the blood–brain barrier owing to their size, charge, and lipophilicity. The sedative effects and cognitive impairment associated with the use of first-generation antihistamines are well documented. Thus, a primary advantage of second-generation antihistamines is that they are nonse-dating or much less sedating than first-generation antihistamines. Although fexofenadine is considered the least sedating of the available nonprescription antihistamines (0% occupation of central nervous system H₁-receptors), cetirizine has the most potential for sedation (26-30%). Both first- and second-generation antihistamines are available in oral preparations. Many first-generation and second-generation antihistamines are available in nonprescription form, including diphenhydramine, loratadine, fexofenadine, and cetirizine. Other antihistamines require a prescription, such as hydroxyzine and cyproheptadine. Antihistamines available as an intranasal spray are azelastine and olopatadine, the latter also functioning as a mast cell stabilizer. The advantage of second-generation antihistamines for the treatment of allergic disease in children because of negligible sedative and anticholinergic effects without a sacrifice in efficacy. Most second-generation antihistamines are effective with convenient once-daily dosing, which may improve therapy adherence. The widespread availability of first-generation antihistamines and their lower cost account for their continued use. The adverse effects most often encountered with second-generation agents include the performance impairment and anticholinergic effects noted with first-generation antihistamines although generally to a lesser degree. The anticholinergic adverse effects encountered may include drying of the mouth and eyes, urinary retention, constipation, excitation, nervousness, palpitations, and tachycardia. Prolongation of the QT interval and ventricular tachycardia (torsades de pointes) has been noted in older no longer available second-generation antihistamines; current antihistamines are not associated with concerning cardiac effects.

### Chromones

Cromolyn sodium and nedocromil sodium are the 2 chromones used to treat allergic disorders. Neither cromolyn nor nedocromil is absorbed well orally, with only 1% of the swallowed dose absorbed. These drugs must be applied topically to the mucosal surface of the target organ to be effective. Both drugs inhibit mast cell degranulation and mediator release. They suppress the activation of a variety of cells, such as eosinophils, neutrophils, macrophages, and epithelial cells. They also suppress the activity of afferent C-type sensory nerve fibers of the nonadrenergic, noncholinergic nervous system. Both drugs inhibit the intracellular increase in free calcium after mast cell activation and phosphorylate a mast cell protein resembling moesin, which is thought to be involved in terminating mediator release.

Cromolyn and nedocromil prevent early- and late-phase allergic responses when administered before allergen exposure. They block allergen-induced increases in bronchial hyperresponsiveness, as well as seasonal increases in non-specific bronchial hyperresponsiveness. With prolonged use, both drugs are capable of reducing bronchial hyperresponsiveness. These drugs have no bronchodilator properties but can inhibit the bronchoconstrictive effects of a variety of stimuli, such as allergen challenge, exercise, hyperventilation with cold air.
ultrasonically nebulized distilled water, and exposure to atmospheric and industrial pollutants.

Cromolyn and nedocromil are used as alternative, but not preferred, therapy for the treatment of mild persistent asthma. Because of their lack of bronchodilator properties, neither drug is useful for the treatment of acute asthma, although both may be used as preventative treatment before vigorous exercise or unavoidable known allergen exposure. Nedocromil is the more potent of the two, but no formulation of nedocromil is currently available for asthma in the United States. Cromolyn is available for the treatment of asthma by prescription as a 1% solution (20 mg/2 mL) for nebulization. The suggested dose for the treatment of asthma is 20 mg of cromolyn 2-4 times/24 hr by nebulization. In numerous studies, cromolyn has been found useful in the treatment of allergic rhinitis and allergic conjunctivitis. Preparations for the nasal and ocular administration of cromolyn are available without a prescription. The suggested dose for the treatment of allergic rhinitis is one spray in each nostril 3 to 4 times daily of a nasal spray containing 5.2 mg of cromolyn per spray (see Table 143-5). For the treatment of allergic conjunctivitis, the suggested dose is 1 drop in each eye 4-6 times a day of a 4% ophthalmic solution. A 2% solution of nedocromil is available by prescription for the treatment of allergic conjunctivitis at a suggested dose of 1-2 drops in each eye twice daily.

The safety of these drugs, even with prolonged administration, is well documented. Because of their favorable safety profile, the monomers are often chosen for use during pregnancy.

Glucocorticoids
Glucocorticoids are widely used in the treatment of allergic disorders because of their potent antiinflammatory properties. The diverse antiinflammatory actions of glucocorticoids are mediated via the glucocorticoid receptor, which is present in all inflammatory effector cells, as well as by direct inhibition of cytokines and mediators. Glucocorticoids are administered topically in ophthalmic preparations, nasal sprays, creams and ointments, metered-dose inhalers, and as a solution for nebulization. Systemic administration is accomplished orally or parenterally. The proper use and efficacy of glucocorticoids in the treatment of allergic disease along with the adverse effects associated with their use are presented in discussions of individual allergic diseases (see Chapters 142-152).

Leukotriene-Modifying Agents
Drugs that alter the leukotriene pathway exert their clinical effects either by inhibiting leukotriene production or by blocking receptor binding. These agents possess mild antiinflammatory properties and exhibit bronchodilator effects. In addition to inhibiting the early- and late-phase allergic responses to inhaled allergen, they diminish bronchoconstriction induced by exercise and exposure to allergen, aspirin, and cold air. Leukotriene-modifying agents have some use in the treatment of asthma (see Chapter 144) and are modestly effective in the treatment of allergic rhinitis (see Chapter 143).

Theophylline
Because of its bronchodilating effects, theophylline (1,3-dimethylxanthine) had been used for yr for the treatment of acute and chronic asthma. The bronchodilator effect of theophylline is likely caused by its action as a phosphodiesterase inhibitor, whereas its ability to antagonize adenosine receptors may play a role in other effects, such as the attenuation of diaphragmatic muscle fatigue and diminishing adenosine-enhanced mast cell mediator release. Theophylline inhibits the immediate- and late-phase pulmonary responses to allergen challenge and exhibits modest protective effects. The therapeutic and toxic effects of theophylline are related to the serum concentration, with the incidence of toxic effects significantly increasing as the serum levels approach and exceed 20 µg/mL. A variety of conditions and medications are capable of increasing or decreasing theophylline metabolism.

The toxic effects of theophylline, ranging from mild nausea, insomnia, irritability, tremors, and headache to cardiac arrhythmias, seizures, and death, necessitate the routine monitoring of theophylline serum levels. Because of the introduction of other effective therapies for the treatment of acute and chronic asthma, the need to monitor drug serum levels routinely, and the potential for significant toxicity, the role of theophylline in the treatment of asthma has contracted significantly (see Chapter 144).

Lodoxamide Tromethamine
A mast cell stabilizer, loxdoxamide tromethamine is more effective than topical cromolyn sodium in alleviating signs and symptoms of allergic ocular disease (see Chapter 147). It is used in children ≥2 yr of age for vernal keratoconjunctivitis, vernal conjunctivitis, and vernal keratitis. Occasional adverse effects have included transient burning or stinging after instillation.

Combination Mast Cell Stabilizer and Antihistamine
Olopatadine, epinastine, and ketotifen are examples of combination mast cell stabilizers and H1-receptor antagonists effective in relieving signs and symptoms of allergic conjunctivitis after topical instillation, although all H1-antihistamines likely have some mast cell stabilizing activity. Dosing is typically twice per day, except of olopatadine, which is dosed once daily.

Antiimmunoglobulin E
Monoclonal antiimmunoglobulin E antibodies (anti-IgE) bind to circulating IgE at a site that prevents its subsequent attachment to the high-affinity receptors for IgE on the mast cell surface. The parenteral administration of anti-IgE reduces free serum IgE concentrations, inhibits skin test responses in allergic patients, suppresses early- and late-phase responses to allergens, and decreases sputum eosinophilia in asthmatic persons. Anti-IgE has a beneficial effect in the treatment of patients with asthma, allergic rhinitis, and urticaria. An anti-IgE preparation (omalizumab) is available for the treatment of children ≥12 yr of age with documented allergen-induced asthma that is inadequately controlled by inhaled corticosteroids. Although this agent is usually well tolerated, local reactions at the injection site and rare episodes of anaphylaxis have been reported. Anti-IgE may also be beneficial in the treatment of other allergic disorders, such as anaphylaxis and food allergy, but more studies are needed. One monoclonal antibody preparation of anti-IgE used in the treatment of adults with peanut allergy resulted in a significant increase in the symptom threshold dose of peanuts. The cost of anti-IgE therapy and need for regular injections requires careful patient selection, special consideration being given to those patients with persistent symptoms despite aggressive pharmacotherapy, significant adverse effects of current therapy, and more than 1 allergic disorder.

Nasal Saline Irrigation
Irrigation with nasal saline can improve symptoms for those with mild allergic rhinitis. Nasal saline irrigation can be used alone or before topical medical. Squeeze bottle kits for this purpose are available over the counter, and typically about 200 mL are irrigated through the nares. Patients may make their own irrigation solutions or buy commercially-prepared solutions. Patients should use boiled or distilled water, as cases of sinus infection with amoebas found in tap water have been reported.

New Therapies
Recombinant soluble interleukin (IL)-4 receptor antagonists exert their effects by binding to and inactivating IL-4 before it can attach to its cell surface receptor. Although initial studies of an inhaled soluble IL-4 receptor in patients with moderate asthma requiring inhaled corticosteroids suggested a beneficial clinical effect, subsequent clinical studies of the effects of anti–IL-4 drugs in the treatment of asthma revealed these therapies to be safe, but clinical efficacy was lacking. Clinical trials of humanized monoclonal anti–IL-5 antibodies administered by injection to asthmatic patients revealed a decrease in circulating eosinophils and sputum eosinophilia, but a lesser reduction of eosinophils from the bronchial submucosa, and this effect was
unaccompanied by a reduction in methacholine reactivity or a suppression of the early- or late-phase response to allergen.

The use of cytokines with antiinflammatory effects in the treatment of allergic disorders is under investigation. Unfortunately, initial studies have not demonstrated a beneficial effect of IL-10 or interleukins in the treatment of asthma. Although studies have documented that IL-12 administration is associated with a decrease in eosinophil accumulation in response to allergen challenge, inhibition of early- and late-phase responses to allergen and decreases in bronchial hyper-reactivity have not been observed. In addition, the high incidence of significant adverse effects encountered with IL-12 administration limits its potential as a viable therapeutic option.

ALLERGEN IMMUNOTHERAPY

Allergen immunotherapy involves administering gradually increasing doses of allergens to a person with allergic disease for the purpose of reducing or eliminating the patient’s adverse clinical response to subsequent natural exposure to those allergens. When properly administered to an appropriate candidate, allergen immunotherapy is a safe, effective form of therapy capable not only of reducing or preventing symptoms but also of potentially altering the natural history of the disease by minimizing disease duration and preventing disease progression. Conventional allergen immunotherapy is given subcutaneously under the direction of an experienced allergist. Sublingual immunotherapy (SLIT) is widely used in Europe for aeroallergens but is not yet FDA-approved in the United States. Sublingual and oral immunotherapy (OOT) for foods are being investigated and are also not FDA-approved.

Indications and Contraindications

Allergen immunotherapy is reserved for patients with an allergic disease demonstrated to respond to this form of therapy, such as seasonal or perennial allergic rhinoconjunctivitis, asthma triggered by allergen exposures, and insect venom sensitivity. Proof of the efficacy of conventional allergen immunotherapy for the treatment of food allergy, atopic dermatitis, latex allergy, and acute or chronic urticaria is lacking; consequently, conventional allergen immunotherapy is not recommended for the treatment of these disorders. Before allergen immunotherapy is considered, sensitivity of the patient to the allergens to be administered should be documented by a positive skin test result or an in vitro test revealing an increased serum level of allergen-specific IgE. The clinical relevance of these allergens should be supported by a history of symptoms upon known exposure or a timing of symptoms that correlates well with suspected allergen exposure, such as the presence of allergic nasal and ocular symptoms throughout the late summer and fall in a child with a positive ragweed skin test response. The duration and severity of the patient’s symptoms, as well as the patient’s preferences, should warrant the expense, effort, and risk associated with the administration of allergen immunotherapy. The presence of disabling symptoms in spite of a trial of allergen avoidance and appropriate medications at a suitable dose should be documented. Venom immunotherapy (VIT) is indicated in children <16 yr of age who have experienced respiratory or cardiovascular symptoms following a sting. For those ≥16 yr, VIT is indicated for any systemic reaction, including those limited to skin but not contiguous from the site of the sting (see Chapter 146).

Other factors that may affect the decision to institute allergen immunotherapy include quality-of-life issues, such as the amount of school missed or medical resource utilization, the age of the patient, and other logistical factors. With the exception of VIT, few data for the efficacy of allergen immunotherapy in children <5 yr of age are available. Allergen immunotherapy is not recommended for children <5 yr of age because of their increased risk of systemic reactions, the special expertise required to treat anaphylaxis in this age group, their potential inability to communicate clearly with the physician in the event of an allergic reaction, and their age-related potential for emotional distress with frequent injections. Other important logistic factors include the willingness of the patient to comply with a schedule of frequent injections over the course of several yr, cost considerations, and the availability of an appropriate medically supervised setting for administering allergen immunotherapy.

Allergen immunotherapy is contraindicated in children undergoing β-blocker therapy as well as those with certain immunologic or autoimmune disorders, allergic bronchopulmonary aspergillosis, hypersensitivity pneumonitis, severe psychiatric disturbance, or a medical condition that would impair the ability to survive an allergic reaction. Pregnancy is a contraindication to the initiation of allergen immunotherapy or dosing increases, although a pregnant adolescent can continue to receive her usual maintenance dose. Patients with unstable asthma should not be started on allergen immunotherapy because of their increased risk for anaphylaxis. Allergen immunotherapy is not used for the treatment of allergic bronchopulmonary aspergillosis or hypersensitivity pneumonitis because it has no benefit. Children receiving β-blockers and angiotensin-converting enzyme-inhibitors are not ideal candidates for allergen immunotherapy because of an increased intensity of allergic reactions and a poor response of conventional therapy to these reactions with β-blocker therapy. Allergen immunotherapy is usually avoided in patients with autoimmune disorders because of the theoretical concern for stimulation of the immune system (formation of antigen–antibody complexes), which might result in disease activation.

Allergen Extracts

The potency of the aqueous extracts used in allergen immunotherapy is affected by numerous factors. Allergens from weed and grass pollens are more easily extracted in aqueous solutions and, as a result, are more potent than extracts obtained from other sources, such as molds, tree pollens, and dust mites. Owing to their complexity, allergen extracts from mold allergens are more variable than extracts from pollen allergens. Refrigeration and appropriate handling of allergen extracts used in allergen immunotherapy are important because degradation of many allergen extracts, such as those from tree, grass, weed pollens, and dust mites, may occur at higher temperatures. Dilute extracts are more susceptible to loss of potency resulting from adherence of allergen to the glass vial than are more concentrated extracts. To combat this effect, preservatives such as 0.03% human serum albumin or 10–50% glycerin may be added to dilute allergen extracts. Some allergen extracts, such as those from cockroaches, dust mites, and molds, contain proteases capable of degrading other allergens in the extract. It is often recommended that these allergens not be mixed with those from tree, grass, and weed pollens. Insect venoms are never mixed with other allergens. When available, the use of standardized allergen extracts is preferred to ensure consistency in dosing and to avoid the variability in allergen content encountered with nonstandardized allergen extracts.

Allergen Extract Administration

The goal of allergen immunotherapy is to increase gradually the dose of allergen extract administered until the injection of an “optimal” maintenance dose containing 4-12 µg of each major allergen in the extract is reached. The mixture of allergen extracts administered during the course of allergen immunotherapy is individually formulated for each patient on the basis of the patient’s documented sensitivities. Although various dosing schedules are used, initial injections are most often given at 5–10–day intervals year-round. Schedules of allergen administration are selected according to the sensitivity of the patient to the allergens in the extract. The most sensitive patients are advanced to a maintenance dose more gradually. Doses of allergen immunotherapy are increased according to a set schedule, although the reaction to the previous injection is also taken into account. A systemic reaction to the previous dose would result in a significant reduction in the next dose, whereas reducing the dose solely on the basis of a large local reaction does not reduce the rate of systemic reactions. Usually 5–6 mo of weekly injections is required to reach the maintenance dose, although it may take longer in highly sensitive patients. Unique schedules for the administration of insect venoms, which differ from those for the administration of other allergens (see Chapter 146), are used. Once the maintenance dose is reached and well tolerated, the interval between injections is increased to a few weeks.
or a month. Because allergen extracts gradually lose potency, the first dose from a fresh replacement vial of maintenance allergen extract is reduced by 25-75% and is then increased in increments weekly until the usual maintenance dose is reached. The recommended length for a course of allergen immunotherapy is 3-5 yr. Insect VIT may be continued indefinitely in patients with a history of life-threatening anaphylaxis. Patients who have not shown improvement after 1 yr of receiving maintenance doses of an appropriate allergen extract are unlikely to benefit, and allergen immunotherapy should be discontinued.

Most patients enjoy a sustained improvement after allergen immunotherapy whereas others experience a gradual return of symptoms. Those who experience a relapse would be expected to respond upon resuming immunotherapy.

**Rush immunotherapy** is the administration of multiple injections either in a single day or over several days in an attempt to reach maintenance dose more rapidly. The risk of adverse reactions, including systemic reactions, is higher than with traditional allergen immunotherapy schedules. Patients to undergo rush immunotherapy are often pretreated with antihistamines and corticosteroids. Children are at even greater risk for adverse reactions with rush immunotherapy; thus the benefits and risks should be fully considered. Preadministration of omalizumab (anti-IgE therapy) reduces the incidence of systemic reactions associated with the use of this form of immunotherapy.

Although allergen immunotherapy is regarded as safe, the potential for anaphylaxis always exists when patients are injected with extracts containing allergens to which they are sensitized. Allergen immunotherapy should be offered in only medical settings where a physician with access to emergency equipment and medications required for the treatment of anaphylaxis is available (see Chapter 149). Allergen injections should never be given at home or by untrained personnel. The patient should remain in the office for 30 min after the injection because most reactions to allergen immunotherapy begin within this time frame. Fatal anaphylaxis triggered by allergen immunotherapy, although rare, is estimated to occur at an incidence of 1 per 2 million injections. The risk of an adverse reaction is increased by dosage errors and the use of rush immunotherapy schedules. Particular caution is warranted when injections from a new vial are given. Patients with exquisite sensitivity or unstable asthma and those experiencing exacerbations of allergic rhinitis or asthma are also at increased risk for adverse reactions to allergen immunotherapy. Precautions to reduce significant adverse reactions include using standardized extracts, having extract vials personalized for each patient, allowing only trained personnel to administer injections, paying careful attention to detail when giving injections, ensuring beforehand that the patient is medically stable, having appropriate medications and equipment available, and requiring the patient to remain in the office for 30 min after each injection. Checking peak flow or spirometry before an injection is advisable for some asthmatic patients. It is also prudent to advise patients to carry self-injectable epinephrine for 24 hr following each injection. While uncommon, delayed systemic reactions have been reported following immunotherapy injections.

Other approaches to immunotherapy are under investigation; they include chemical or genetic manipulation of the allergen and linking of the principle allergenic moiety of a relevant allergen to a highly active adjuvant, such as an immunostimulatory sequence mimicking patterns of bacterial DNA.

Local nasal immunotherapy is administered by having the patient spray allergen solutions into the nose at scheduled intervals. Although symptom amelioration has been noted, a lack of a significant systemic immunologic response has decreased interest in pursuing this form of therapy. SLIT involves the sublingual administration of high-dose allergen, which is then swallowed. SLIT is now FDA-approved for a limited number of pollens, and its use is expected to increase given its favorable safety profile and convenience of administration.

**Efficacy**

The positive impact of allergen immunotherapy on seasonal or perennial allergic rhinitis or rhinoconjunctivitis is well documented. In regard to the treatment of allergic rhinitis, birch, mountain cedar, grass, ragweed, and *Cladosporium* are allergens for which allergen immunotherapy has been effective. Effectiveness of allergen immunotherapy with other allergens commonly used for the treatment of allergic rhinitis is inconclusive. Most of the controlled trials examining the effects of allergen immunotherapy on seasonal or perennial allergic asthma also report favorable results. A meta-analysis of 20 trials examining the effects of allergen immunotherapy on allergic asthma revealed a significant increase in the odds for improvement after treatment along with fewer symptoms, improved pulmonary functions, less need for medication, and a reduction in bronchial hyperreactivity. The most convincing data for the benefit of allergen immunotherapy in the treatment of allergic asthma are available for birch, mountain cedar, grass, ragweed, and dust mite with less conclusive but suggestive data available for *Cladosporium*, *Alternaria*, and cat allergens. Studies examining the effects of allergen immunotherapy in the treatment of patients with allergic rhinitis and allergic asthma have documented increases in circulating allergen-specific IgG and decreases in allergen-specific IgE after treatment. Reductions in sensitivity to administered allergens have been demonstrated in nasal and bronchial challenges. These studies have often shown that the late-phase response after allergen challenge is ablated or significantly reduced. The protective benefit as well as the safety of VIT in patients with sensitivity to *Hymenoptera* venoms has also been well documented in several large studies. The efficacy of allergen immunotherapy for the treatment of urticaria and latex allergy has not been documented. Dust mite allergen immunotherapy may be helpful in patients with atopic dermatitis. Studies using OIT, involving the oral administration of gradually increasing doses of a food allergen under close medical observation followed by a prolonged maintenance phase of daily fixed-dose food allergen administration at home, has been shown to desensitize patients but has not yet proven to induce tolerance. Although still under investigation, OIT and perhaps SLIT are promising therapeutic approaches to the treatment of food allergy in the future.

*Bibliography is available at Expert Consult.*
Bibliography

Allergic rhinitis (AR) is an inflammatory disorder of the nasal mucosa marked by nasal congestion, rhinorrhea, and itching, often accompanied by sneezing and conjunctival inflammation. Its recognition as a major chronic respiratory disease of children rests largely on its high prevalence, detrimental effects on quality of life and school performance, and comorbidities. Children with AR often have related conjunctivitis, sinusitis, otitis media, serous otitis, hypertrophic tonsils and adenoids, and eczema. Childhood AR is associated with a 3-fold increase in risk for asthma at an older age. Over the past 50 yr an upsurge in AR has been observed throughout the world, particularly in areas where its prevalence previously had been low. In prosperous societies, 20-40% of children suffer from AR. The symptoms may appear in infancy; with the diagnosis generally established by the time the child reaches age 6 yr. The prevalence peaks late in childhood.

Risk factors include family history of atopy and serum immunoglobulin (Ig) E higher than 100 IU/mL before age 6 yr. Early life exposures and/or their absence have a profound influence on the development of the allergic phenotype. The risk increases in children whose mothers smoke heavily, even before delivery and especially before the infants are 1 yr old, and those with heavy exposure to indoor allergens. A critical period exists early in infancy when the genetically susceptible individual is at greatest risk of sensitization. Delivery by
ETIOLOGY AND CLASSIFICATION

Two factors necessary for expression of AR are sensitivity to an allergen and the presence of the allergen in the environment. AR classification as seasonal or perennial is giving way to the designations intermittent and persistent. The 2 sets of terms are based on different suppositions, but inhalant allergens are the main cause of all forms of AR irrespective of terminology. AR may also be categorized as mild-intermittent, moderate-severe intermittent, mild-persistent, and moderate-severe persistent (Fig. 143-1). The symptoms of intermittent AR occur on <4 days per week or for <4 consecutive weeks. In persistent AR symptoms occur on >4 days per week and/or for >4 consecutive weeks.

The symptoms are considered mild when they are not troublesome, the sleep is normal, there is no impairment in daily activities, and no incapacity at work or school. Severe symptoms result in sleep disturbance, and impairment in daily activities and school (Fig. 143-1).

Intermittent climates, airborne pollen responsible for exacerbation of intermittent AR appear in distinct phases: trees pollinate in the spring, grasses in the early summer, and weeds in the late summer. In temperate climates, mold spores persist outdoors only in the summer, but in warm climates throughout the year. Symptoms of intermittent AR typically cease with the appearance of frost. Knowledge of the time of occurrence of symptoms, of the regional patterns of pollination and mold sporulation, and of the patient’s specific IgE is necessary for the recognition of the cause of intermittent AR. Persistent AR is most often associated with the indoor allergens: house dust mites, animal danders, mice, and cockroaches. Cat and dog allergies are of major importance in the United States. The allergens from saliva and sebaceous secretions may remain airborne for a prolonged time. The ubiquitous major cat allergen, Fel d 1, may be carried on cat owners’ clothing into such “cat-free” settings as schools and hospitals.

PATHOGENESIS

The exposure of an atopic host to an allergen leads to specific IgE production. The clinical reactions on reexposure to the allergen have been designated as early-phase and late-phase allergic responses. Bridging of the IgE molecules on the surface of mast cells by allergen initiates early-phase allergic response, characterized by degranulation of mast cells and release of preformed and newly generated inflammatory mediators including histamine, prostaglandin 2, and the cysteinyi leukotrienes. Late-phase allergic response appears 4-8 hr following allergen exposure. Inflammatory cells, including basophils, eosinophils, neutrophils, mast cells, and mononuclear cells, infiltrate the nasal mucosa. Eosinophils release proinflammatory mediators, including cysteinyi leukotrienes, cationic proteins, eosinophil peroxidase, and major basic protein, and serve as a source of interleukin (IL)-3, IL-5, granulocyte-macrophage colony-stimulating factor, and IL-13. Repeated intranasal introduction of allergens causes “priming”—a more brisk response even with a lesser provocation. Over the course of an allergen season a multifold increase in submucosal mast cells takes place. These cells, once thought to have a role exclusively in the early-phase allergic response, have an important function in sustaining chronic allergic disease. Allergens, autoantigens, and components of superimposed infectious agents activate the immune system.

CLINICAL MANIFESTATIONS

Symptoms of AR may be ignored or mistakenly attributed to a respiratory infection. Older children blow their noses, but younger children tend to sniff and snort. Nasal itching brings on grimacing, twitching, and picking of the nose that may result in epistaxis. Children with AR often perform the allergic salute, an upward rubbing of the nose with an open palm or extended index finger. This maneuver relieves itching and briefly unblocks the nasal airway. It also gives rise to the nasal crease, a horizontal skin fold over the bridge of the nose. The diagnosis of AR is based on symptoms in the absence of an upper respiratory tract infection and structural abnormalities. Typical complaints include intermittent nasal congestion, itching, sneezing, clear rhinorrhea, and conjunctival irritation. Symptoms increase with greater exposure to the responsible allergen. The patients may lose their sense of smell and taste. Some experience headaches, wheezing, and coughing. Nasal congestion is often more severe at night, causing mouth breathing and snoring, interfering with sleep, and arousing irritability.

Signs on physical exam include abnormalities of facial development, dental malocclusion, and the “allergic gape” or continuous open-mouth breathing, chapped lips, “allergic shiners” (dark circles under the eyes), and the transverse nasal crease. Conjunctival edema, itching, tearing, and hyperemia are frequent findings. A nasal exam performed with a source of light and a speculum may reveal clear nasal secretions; edematous, boggy, and bluish mucus membranes with little or no erythema; and swollen turbinates that may block the nasal airway. It may be necessary to use a topical decongestant to perform an adequate examination. Thick, purulent nasal secretions indicate the presence of infection.

DIFFERENTIAL DIAGNOSIS

Evaluation of AR calls for a thorough history, including details of the patient’s environment and diet and family history of allergic conditions such as eczema, asthma, and AR, physical examination, and laboratory evaluation. The history and laboratory findings provide clues to the provoking factors. Symptoms that include sneezing, rhinorrhea, nasal itching, and congestion and the laboratory findings of elevated IgE, specific IgE antibodies, and positive allergy skin test results typify AR. Intermittent AR differs from persistent AR by history and skin test results. Nonallergic rhinitides cause sporadic symptoms. Their causes are often unknown. Nonallergic inflammatory rhinitis with eosinophils imitates AR in presentation and response to treatment, but without elevated IgE antibodies. Vasomotor rhinitis is characterized by excessive responsiveness of the nasal mucosa to physical stimuli. Other nonallergic conditions, such as infectious rhinitis; structural problems, including nasal polyps and septal deviation; rhinitis medicamentosa (caused by the overuse of topical vasoconstrictors); hormonal rhinitis...

</table>

Associated with pregnancy or hypothyroidism; neoplasms; vasculitides; and granulomatous disorders may mimic AR (Table 143-1, Fig. 143-2).

Occupational risks for rhinitis include exposure to allergens (grain dust, insects, latex, enzymes) and irritants (wood dust, paint, solvents, smoke, cold air).

### Complications

AR is frequently associated with complications and comorbid conditions. Children with AR experience frustration over their appearance. Allergic conjunctivitis, characterized by itching, redness and swelling of the conjunctivae, has been reported in at least 20% of the population and in more than 70% of patients with AR, most frequently in older children and young adults. The 2 conditions share pathophysiologic mechanisms and epidemiologic characteristics (see Chapter 147). Chronic sinusitis is a common complication of AR, sometimes associated with purulent infection, but most patients have negative bacterial cultures despite marked mucosal thickening, and sinus opacification. The inflammatory process is characterized by marked eosinophilia. Allergens, possibly fungal, are the inciting agents. The sinusitis of triad asthma (asthma, sinusitis with nasal polyposis, and aspirin sensitivity) often responds poorly to therapy. Patients who undergo repeated endoscopic surgery derive diminishing benefit with each successive procedure.

Rhinitis that coexists with asthma may be taken too lightly or completely overlooked. Up to 78% of patients with asthma have AR, and 38% of patients with AR have asthma. Aggravation of AR coincides with exacerbation of asthma, and treatment of nasal inflammation reduces bronchospasm, asthma-related emergency department visits, and hospitalizations. Postnasal drip associated with AR commonly causes persistent or recurrent cough. Eustachian tube obstruction and middle ear effusion are frequent complications. Chronic allergic inflammation causes hypertrophy of adenoids and tonsils that may be associated with eustachian tube obstruction, serous effusion, otitis media, and obstructive sleep apnea. AR is linked to snoring in children. The association between rhinitis and sleep abnormalities and subsequent daytime fatigue is well documented.

The Pediatric Rhinoconjunctivitis Quality of Life Questionnaire (PRQLQ) is suitable for children 6-12 yr old, and the Adolescent Rhinoconjunctivitis Quality of Life Questionnaire (ARQLQ) is appropriate for patients 12-17 yr of age. Children with rhinitis have anxiety and physical, social, and emotional issues that affect learning and the ability to integrate with peers. The disorder contributes to headaches and fatigue, limits daily activities, and interferes with sleep. There is evidence of impaired cognitive functioning and learning that may be exacerbated by the adverse effects of sedating medications. Rhinitis is an important cause of lost school attendance, resulting in more than 2 million days of absence in the United States annually.

### Laboratory Findings

Epicutaneous skin tests provide the best method for detection of allergen-specific IgE (positive predictive value of 48.7% for the epidemiologic diagnosis of AR). They are inexpensive and sensitive, and the risks and discomfort are minimal. Responses to seasonal respiratory allergens are rare before 2 seasons of exposure, and children <1 yr seldom display positive skin test responses to these allergens. To avoid false-negative results, montelukast should be withheld for 1 day, most sedating antihistamine preparations for 3-4 days, and non-sedating antihistamines for 5-7 days. Serum immunoassays for specific IgE to allergens provide a suitable alternative (positive predictive value 43.5%) for patients with dermatographism or extensive dermatitis, those taking medications that interfere with mast cell degranulation, others at high risk for anaphylaxis, and some who cannot cooperate with the procedure. Presence of eosinophils in nasal smear supports the diagnosis of AR, and of neutrophils infectious rhinitis. Eosinophilia and measurements of total serum IgE concentrations have relatively low sensitivity.

### Treatment

Safe and effective prevention and/or relief of symptoms are the current goals of treatment. Specific measures to limit indoor allergen exposure may reduce the risk of sensitization and symptoms of allergic respiratory disease. Sealing the patient’s mattress, pillow, and covers in allergen-proof encasings reduces the exposure to mite allergen. Bed linen and blankets should be washed every week in hot water (>54.4°C [130°F]). The only effective measure for avoiding animal allergens in the home is the removal of the pet. Avoidance of pollen and outdoor molds can be accomplished by staying in a controlled environment. Air conditioning allows for keeping windows and doors closed, reducing the pollen exposure. High-efficiency particulate air filters lower the counts of airborne mold spores.

Oral antihistamines help reduce sneezing, rhinorrhea and ocular symptoms. Administered as needed they provide acceptable treatment for mild-intermittent disease. Antihistamines have been classified as first generation (relatively sedating) or second generation (relatively non-sedating). Antihistamines usually are administered by mouth, but they are also available for topical ophthalmic and intranasal use. Both first- and second-generation antihistamines are available as nonprescription drugs. Second-generation antihistamines are preferred
because they cause less sedation. Preparations containing pseudoephedrine, typically in combination with other agents, are used for relief of nasal and sinus congestion and pressure and other symptoms such as rhinorrhea, sneezing, lacrimation, itching eyes, oronasopharyngeal itching, and cough. Pseudoephedrine is available without prescription (generally in fixed combination with other agents such as first-generation antihistamines: brompheniramine, chlorpheniramine, triprolidine; second-generation antihistamines: desloratadine, fexofenadine, loratadine; antipyretics: acetaminophen, ibuprofen; antitussives: diphenhydramine, dextromethorphan; antitussives; guaifenesin, dextromethorphan; antitussives; methscopolamine). Pseudoephedrine is an oral vasoconstrictor disfavored for causing irritability and insomnia and for its association with infant mortality. Because younger children (2-3 yr of age) are at increased risk of overdosage and toxicity, some manufacturers of oral nonprescription cough and cold preparations have voluntarily revised their product labeling to warn against the use of preparations containing pseudoephedrine for children younger than 4 yr. Pseudoephedrine is misused as a starting material for the synthesis of methamphetamine and methcathinone. Oral agents for treatment of AR are shown in Tables 143-2, 143-3, and 143-4.

The anticholinergic nasal spray ipratropium bromide is effective for the treatment of serous rhinorrhea (Table 143-5). Intranasal decongestants (oxytetracycline and phenylephrine) should be used for less than 5 days, not to be repeated more than once a month in order to avoid rebound nasal congestion. Sodium cromoglycate (available as a nonprescription drug) is effective but requires frequent administration, q4h. Leukotriene-modifying agents have a modest effect on rhinorrhea and nasal blockage (see Chapter 144 for additional indications and side effects). Nasal saline irrigation is a good adjunctive option with all other treatments of AR. Patients with more persistent, severe symptoms require intranasal corticosteroids, the most effective therapy for AR, a treatment that may be beneficial also for concomitant allergic conjunctivitis (Table 143-6). These agents reduce the symptoms of AR with eosinophilic inflammation, but not those of rhinitis associated with neutrophils or free of inflammation. Beclomethasone, triamcinolone, and flunisolide are absorbed from the gastrointestinal tract, as well as from the respiratory tract; budesonide, fluticasone, mometasone, and ciclesonide offer greater topical activity with lower systemic exposure. More severely affected patients may benefit from simultaneous treatment with oral antihistamines and intranasal corticosteroids.

Allergy immunotherapy is an effective treatment for AR and allergic conjunctivitis. In addition to reducing symptoms, it may change the course of allergic disease and induce allergen-specific immune tolerance. Immunotherapy administered by subcutaneous injection should be considered for children in whom IgE-mediated allergic symptoms cannot be adequately controlled by avoidance and medication, especially in the presence of comorbid conditions. Sublingual immunotherapy has been used successfully in Europe and South America. Sublingual immunotherapy is considered investigational in the United States, and there are no extracts for sublingual administration licensed by the FDA. Omalizumab (anti-IgE antibody) given subcutaneously has a dose-dependent effect on seasonal AR; its role compared with standard therapy has yet to be determined.

Typically, treatment of AR with oral antihistamines and inhaled corticosteroids provides sufficient relief for most cases of coexisting allergic conjunctivitis. If it fails, additional therapies directed primarily to allergic conjunctivitis may be added (see Chapter 147). Intranasal corticosteroids are of some value for the treatment of ocular symptoms, but opthalmic corticosteroids remain the most potent pharmacologic agents for ocular allergy. They carry the risk of adverse effects, such as delayed wound healing, secondary infection, elevated intraocular

pressure, and formation of cataracts. These agents are only suited for the treatment of allergic conjunctivitis that does not respond to the medications discussed above. Sound practice calls for the assistance of an ophthalmologist.

**PROGNOSIS**

Therapy with non-sedating antihistamines and topical corticosteroids, when taken faithfully, significantly improves health-related quality-of-life measures in patients. The reported rates of remission among children are between 10% and 23%. Pharmacotherapy that will target cells and cytokines involved in inflammation and treat allergy as a systemic process is on the horizon, and more selective targeting of drugs based on the development of specific biomarkers and genetic profiling may soon be realized.

*Bibliography is available at Expert Consult.*
Bibliography

Asthma is a chronic inflammatory condition of the lung airways resulting in episodic airflow obstruction. This chronic inflammation heightens the twitchiness of the airways—airways hyperresponsiveness (AHR)—to provocative exposures. Asthma management is aimed at reducing airways inflammation by minimizing proinflammatory environmental exposures, using daily controller antiinflammatory medications, and controlling comorbid conditions that can worsen asthma. Less inflammation typically leads to better asthma control, with fewer exacerbations and decreased need for quick-reliever asthma medications. Nevertheless, exacerbations can still occur. Early intervention with systemic corticosteroids greatly reduces the severity of such episodes. Advances in asthma management and, especially, pharmacotherapy enable all but the uncommon child with difficult asthma to live normally.

**Etiology**

Although the cause of childhood asthma has not been determined, a combination of environmental exposures and inherent biologic and genetic susceptibilities has been implicated (Fig. 144-1). In the susceptible host, immune responses to common airways exposures (e.g., respiratory viruses, allergens, tobacco smoke, air pollutants) can stimulate prolonged, pathogenic inflammation and aberrant repair of injured airways tissues. Lung dysfunction (AHR, reduced airflow) and airway remodeling develop. These pathogenic processes in the growing lung during early life adversely affect airways growth and differentiation, leading to altered airways at mature ages. Once asthma has developed, ongoing inflammatory exposures appear to worsen it, driving disease persistence and increasing the risk of severe exacerbations.

**Genetics**

To date, more than 100 genetic loci have been linked to asthma, although relatively few have consistently been linked to asthma in different study cohorts. Replicating variants include genetic loci containing proallergic, proinflammatory genes. Because epigenetic marks are heritable, are responsive to environmental exposures, and can result in rapid and persistent changes in gene expression it is conceivable that epigenetic modification of genes play a role in the transmission of asthma.

**Figure 144-1 Etiology and pathogenesis of asthma.** A combination of environmental and genetic factors in early life shape how the immune system develops and responds to ubiquitous environmental exposures. Respiratory microbes, inhaled allergens, and toxins can injure the lower airways target the disease process to the lungs. Aberrant immune and repair responses to airways injury underlie persistent disease. AHR, airways hyperresponsiveness; ETS, environmental tobacco smoke.

**Environment**

Recurrent wheezing episodes in early childhood are associated with common respiratory viruses, especially common cold rhinoviruses, and also respiratory syncytial virus, influenza virus, adenovirus, parainfluenza virus, and human metapneumovirus. This association implies that host features affecting immunologic host defense, inflammation, and the extent of airways injury from ubiquitous viral pathogens underlie susceptibility to recurrent wheezing in early childhood. Other airways exposures can also exacerbate ongoing airways inflammation, increase disease severity, and drive asthma persistence. Home allergen exposures in sensitized individuals can initiate airways inflammation and hypersensitivity to other irritant exposures, and are strongly linked to disease severity and persistence. Consequently, eliminating the offending allergen(s) can lead to resolution of asthma symptoms and can sometimes cure asthma. Environmental tobacco smoke and common air pollutants can aggravate airways inflammation and increase asthma severity. Cold, dry air, hyperventilation from physical play or exercise, and strong odors can trigger bronchoconstriction. Although many exposures that trigger and aggravate asthma are well recognized, the causal environmental features underlying the development of host susceptibilities to the various common airway exposures are not well defined.

**Epidemiology**

Asthma is a common chronic disease, causing considerable morbidity. In 2011, more than 10 million children (14% of U.S. children) had ever been diagnosed with asthma, with 70% of this group reporting current asthma. Male gender and living in poverty are demographic risk factors for having childhood asthma in the U.S. Fifteen percent of boys
compared to 13% of girls have had asthma; and 18% of all children living in poor families (incomes less than $25,000 per year), compared to 12% of children in families not classified as poor, have had asthma.

Childhood asthma is among the most common causes of childhood emergency department visits, hospitalizations, and missed school days. In the United States in 2006, childhood asthma accounted for 593,000 emergency department visits, 155,000 hospitalizations, and 167 deaths. A disparity in asthma outcomes links high rates of asthma hospitalization and death with poverty, ethnic minorities, and urban living. In the past 2 decades, black children have had 2-7 times more emergency department visits, hospitalizations, and deaths as a result of asthma than nonblack children. Although current asthma prevalence is higher in black than in nonblack U.S. children (in 2011, 16.5% vs 8.1% for white and 9.8% for Latino children), prevalence differences cannot fully account for this disparity in asthma outcomes.

Worldwide, childhood asthma appears to be increasing in prevalence, despite considerable improvements in our management and pharmacopeia to treat asthma. Numerous studies conducted in different countries have reported an increase in asthma prevalence of approximately 50% per decade. Globally, childhood asthma prevalence varies widely in different locales. A study of childhood asthma prevalence in 233 centers in 97 countries (International Study of Asthma and Allergies in Childhood, Phase 3) found a wide range in the prevalence of current wheeze in 6-7 yr (2.4-37.6%) and 13-14 yr old children (0.8-32.6%). Asthma prevalence correlated well with reported allergic rhinoconjunctivitis and atopic eczema prevalence. Childhood asthma seems more prevalent in modern metropolitan locales and more affluent nations, and is strongly linked with other allergic conditions. In contrast, children living in rural areas of developing countries and farming communities with domestic animals are less likely to experience asthma and allergy.

Approximately 80% of all asthmatic patients report disease onset prior to 6 yr of age. However, of all young children who experience recurrent wheezing, only a minority go on to have persistent asthma in later childhood. Early childhood risk factors for persistent asthma have been identified (Table 144-1) and have been described as major (parent asthma, eczema, inhalant allergen sensitization) and minor (allergic rhinitis, wheezing apart from colds, ≥4% peripheral blood eosinophils, food allergen sensitization) risk factors. Allergy in young children with recurrent cough and/or wheeze is the strongest identifiable factor for the persistence of childhood asthma.

**Types of Childhood Asthma**

There are 2 common types of childhood asthma based on different natural courses: (1) **recurrent wheezing** in early childhood, primarily triggered by common respiratory viral infections, usually resolves during the preschool/lower school years; and (2) **chronic asthma** associated with allergy that persists into later childhood and often adulthood (Table 144-2). School-age children with mild-moderate persistent asthma generally improve as teenagers, with some (~40%) developing intermittent disease. Milder disease is more likely to remit. Inhaled corticosteroid controller therapy for children with persistent asthma does not alter the likelihood of outgrowing asthma in later childhood; however, because children with asthma generally improve with age, their need for controller therapy subsequently lessens and often resolves. Progressive decline in lung function can be a feature of severe, persistent disease.

Asthma is also classified by disease severity (e.g., intermittent or persistent [mild, moderate, or severe]) or control (e.g., well, not well, or very poorly controlled), especially for asthma management purposes. Because most children with asthma can be well controlled with conventional management guidelines, children with asthma can also be characterized according to treatment response and medication requirements as being: (1) easy-to-treat: well controlled with low

levels of controller therapy; (2) difficult-to-treat: well controlled with multiple and/or high levels of controller therapies; (3) exacerbators: despite being well controlled, continue to have severe exacerbations; and (4) refractory asthma: continue to have poorly controlled asthma despite multiple and high levels of controller therapies (Table 144-2). Different airways pathologic processes, causing airways inflammation, AHR, and airways congestion and blockage, are believed to underlie these different types of asthma.

**PATHOGENESIS**

Airflow obstruction in asthma is the result of numerous pathologic processes. In the small airways, airflow is regulated by smooth muscle encircling the airway lumen; bronchoconstriction of these bronchiolar muscular bands restricts or blocks airflow. A cellular inflammatory infiltrate and exudates distinguished by eosinophils, but also including other inflammatory cell types (neutrophils, monocytes, lymphocytes, mast cells, basophils), can fill and obstruct the airways and induce epithelial damage and desquamation into the airways lumen. Helper T lymphocytes and other immune cells that produce proallergic, proinflammatory cytokines ( interleukin [IL]-4, IL-5, IL-13), and chemokines (eotaxins) mediate this inflammatory process. Pathogenic immune responses and inflammation may also result from a breach in normal immune regulatory processes (such as regulatory T lymphocytes that produce IL-10 and transforming growth factor-β) that dampen effector immunity and inflammation when they are no longer needed. Hypersensitivity or susceptibility to a variety of provocative exposures or triggers (Table 144-3) can lead to airways inflammation, AHR, edema, basement membrane thickening, subepithelial collagen deposition, smooth muscle and mucous gland hypertrophy, and mucus hypersecretion—all processes that contribute to airflow obstruction.

**CLINICAL MANIFESTATIONS AND DIAGNOSIS**

Intermittent dry coughing and expiratory wheezing are the most common chronic symptoms of asthma. Older children and adults report associated shortness of breath and chest congestion and tightness; younger children are more likely to report intermittent, nonfocal chest pain. Respiratory symptoms can be worse at night, associated with sleep, especially during prolonged exacerbations triggered by respiratory infections or inhalant allergens. Daytime symptoms, often linked with physical activities (exercise-induced) or play, are reported with greatest frequency in children. Other asthma symptoms in children can be subtle and non-specific, including self-imposed limitation of physical activities, general fatigue (possibly resulting from sleep disturbance), and difficulty keeping up with peers in physical activities. Asking about previous experience with asthma medications (bronchodilators) may provide a history of symptomatic improvement with treatment that supports the diagnosis of asthma. Lack of improvement with bronchodilator and corticosteroid therapy is inconsistent with underlying asthma and should prompt more vigorous consideration of asthma-masquerading conditions.

Asthma symptoms can be triggered by numerous common events or exposures: physical exertion and hyperventilation (laughing), cold or dry air, and airways irritants (see Table 144-3). Exposures that induce airways inflammation, such as infections with common respiratory pathogens (rhinovirus, respiratory syncytial virus, metapneumovirus, parainfluenza virus, influenza virus, adenovirus, *Mycoplasma pneumoniae*, Chlamydia pneumoniae), and inhaled allergens in sensitized children, also increase AHR to dry cold air and irritant exposures. An environmental history is essential for optimal asthma management (see Chapter 141).

The presence of risk factors, such as a history of other allergic conditions (allergic rhinitis, allergic conjunctivitis, atopic dermatitis, food allergies), parental asthma, and/or symptoms apart from colds, supports the diagnosis of asthma. During routine clinic visits, children with asthma commonly present without abnormal signs, emphasizing the importance of the medical history in diagnosing asthma. Some may exhibit a dry, persistent cough. The chest findings are often normal. Deeper breaths can sometimes elicit otherwise undetectable wheezing. In clinic, quick resolution (within 10 min) or convincing improvement in symptoms and signs of asthma with administration of a short-acting inhaled ß-agonist (SABA; e.g., albuterol) is supportive of the diagnosis of asthma.

During asthma exacerbations, expiratory wheezing and a prolonged exhalation phase can usually be appreciated by auscultation. Decreased breath sounds in some of the lung fields, commonly the right lower posterior lobe, are consistent with regional hypoventilation caused by airways obstruction. Rhonchi and crackles (or rales) can sometimes be heard, resulting from excess mucus production and inflammatory exudate in the airways. The combination of segmental crackles and poor breath sounds can indicate lung segmental atelectasis that is difficult to distinguish from bronchial pneumonia and can complicate acute asthma management. In severe exacerbations, the greater extent of airways obstruction causes labored breathing and respiratory distress, which manifests as inspiratory and expiratory wheezing, increased prolongation of exhalation, poor air entry, suprasternal and intercostal retractions, nasal flaring, and accessory respiratory muscle use. In extremis, airflow may be so limited that wheezing cannot be heard (Table 144-4).

**DIFFERENTIAL DIAGNOSIS**

Many childhood respiratory conditions can present with symptoms and signs similar to those of asthma (Table 144-5). Besides asthma, other common causes of chronic, intermittent coughing include gastroesophageal reflux (GER) and rhinosinusitis. Both GER and chronic sinusitis can be challenging to diagnose in children. Often, GER is clinically silent in children, and children with chronic sinusitis do not report sinusitis-specific symptoms, such as localized sinus pressure and

tenderness. In addition, both GER and rhinosinusitis are often comorbid with childhood asthma and, if not specifically treated, may make asthma difficult to manage.

In early life, chronic coughing and wheezing can indicate recurrent aspiration, tracheobronchomalacia, a congenital anatomic abnormality of the airways, foreign-body aspiration, cystic fibrosis, or bronchopulmonary dysplasia.

In older children and adolescents, vocal cord dysfunction (VCD) can manifest as intermittent daytime wheezing (Table 144-6). In this condition, the vocal cords involuntarily close inappropriately during inspiration and sometimes exhalation, producing shortness of breath, coughing, throat tightness, and often audible laryngeal wheezing and/or stridor. In most cases of VCD, spirometric lung function testing reveals “truncated” and inconsistent inspiratory and expiratory flow-volume loops, a pattern that differs from the reproducible pattern of airflow limitation in asthma that improves with bronchodilators. VCD can coexist with asthma. Flexible rhinolaryngoscopy in the patient with symptomatic VCD can reveal paradoxical vocal cord movements with anatomically normal vocal cords. This condition can be well managed with specialized speech therapy training in the relaxation and control of vocal cord movement. Furthermore, treatment of underlying causes of vocal cord irritability (e.g., high GER/aspiration, allergic rhinitis, rhinosinusitis, asthma) can improve VCD. During acute VCD exacerbations, in addition to relaxation breathing techniques in conjunction with inhalation of heliox (a mixture of 70% helium and 30% oxygen) can relieve vocal cord spasm and VCD symptoms.

Exercise-induced laryngeal obstruction must be considered in children with a presumptive diagnosis of exercise-induced asthma. The diagnosis is confirmed by continuous video laryngoscopy during exercise.

In some locales, hypersensitivity pneumonitis (farming communities, homes of bird owners), pulmonary parasitic infestations (rural areas of developing countries), or tuberculosis may be common causes of chronic coughing and/or wheezing. Rare asthma-masquerading conditions in childhood include bronchiolitis obliterans, interstitial lung diseases, primary ciliary dyskinesias, humoral immune deficiencies, allergic bronchopulmonary mycoses, congestive heart failure, mass lesions in or compressing the larynx, trachea, or bronchi, and coughing and/or wheezing that is an adverse effect of medication. Chronic pulmonary diseases often produce clubbing, but clubbing is a very unusual finding in childhood asthma.

**LABORATORY FINDINGS**

Lung function tests can help to confirm the diagnosis of asthma and to determine disease severity.

**Pulmonary Function Testing**

Forced expiratory airflow measures are helpful in diagnosing and monitoring asthma and in assessing efficacy of therapy. Lung function testing is particularly helpful in children with asthma who are poor perceivers of airflow obstruction or when physical signs of asthma do not occur until airflow obstruction is severe.

*Notes:
- The presence of several parameters, but not necessarily all, indicates the general classification of the exacerbation.
- Many of these parameters have not been systematically studied, especially as they correlate with each other. Thus, they serve only as general guides.
- The emotional impact of asthma symptoms on the patient and family is variable but must be recognized and addressed and can affect approaches to treatment and follow-up.
- *Normal breathing rates in children by age: 2-12 mo, <60 breaths/min; 2-12 mo, <60 breaths/min; 1-5 yr, <40 breaths/min; 6-8 yr, <30 breaths/min.*

Many asthma guidelines promote spirometric measures of airflow and lung volumes during forced expiratory maneuvers as standard for asthma assessment. Spirometry is a helpful objective measure of airflow limitation (Fig. 144-2). Spriometry is an essential assessment tool in children who are at risk for severe asthma exacerbations and those who have poor perception of asthma symptoms. Knowledgeable personnel are needed to perform and interpret findings of spirometry tests. Valid spirometric measures depend on a patient's ability to properly perform a full, forceful, and prolonged expiratory maneuver during forced expiratory maneuvers as standard techniques. The tests are reproducible within 5% on 3 measurements, and the highest value taken as the measured report effort of the 3 is used. This standard utilization of the highest of 3 reproducible efforts is indicative of the effort dependence of reliable spirometric testing.

In asthma, airways blockage results in reduced airflow with forced exhalation (see Fig. 144-2). Because asthmatic patients typically have hyperinflated lungs, FEV<sub>1</sub> can be simply adjusted for full expiratory volume—the forced vital capacity (FVC)—with an FEV<sub>1</sub>/FVC ratio. Generally, an FEV<sub>1</sub>/FVC ratio <0.80 indicates significant airflow obstruction (Table 144-7). The onset of exercise-induced airflow limitation (Fig. 144-2) should be reproducible within 5% on 3 measurements, and the highest value taken as the measured report effort of the 3 is used. This standard utilization of the highest of 3 reproducible efforts is indicative of the effort dependence of reliable spirometric testing.

treadmill challenges in the clinic are not completely reliable and can miss exertional asthma that can be demonstrated on the playing field; and second, exercise challenges can induce severe exacerbations in at-risk patients. Careful patient selection for exercise challenges and preparedness for severe asthma exacerbations are required.

Measuring exhaled nitric oxide (FeNO), a marker of airway inflammation in allergy-associated asthma, may possibly help adjust anti-inflammatory management and confirm the diagnosis of asthma.

**Peak expiratory flow (PEF) monitoring** devices provide simple and inexpensive home-use tools to measure airflow and can be helpful in a number of circumstances (Fig. 144-3). Similarly to spirometry in clinics, poor perceivers of asthma can benefit by monitoring PEFs at home to assess their airflow as an indicator of asthma control or problems. PEF devices vary in the ability to detect airflow obstruction: they are generally less sensitive and reliable than spirometry to detect airflow obstruction such that, in some patients, PEF values decline only when airflow obstruction is severe. Therefore, PEF monitoring should be started by measuring morning and evening PEFs (best of 3 attempts) for several weeks for patients to practice the technique, to determine diurnal variation and a “personal best,” and to correlate PEF values with symptoms (and ideally spirometry). Diurnal variation in PEF >20% is consistent with asthma (see Fig. 144-3 and Table 144-7).

**Radiology**

The findings of chest radiographs (posteroanterior and lateral views) in children with asthma often appear to be normal, aside from subtle and nonspecific findings of hyperinflation (e.g., flattening of the diaphragms) and peribronchial thickening (Fig. 144-4). Chest radiographs can help identify abnormalities that are hallmarks of asthma masqueraders (aspiration pneumonitis, hyperlucent lung fields in bronchiolitis obliterans) and complications during asthma exacerbations (atelectasis, pneumomediastinum, pneumothorax). Some lung abnormalities can be better appreciated with high-resolution, thin-section chest CT scans. Bronchiectasis, which is sometimes difficult to appreciate on chest radiograph but is clearly seen on CT scan, implies an asthma masquerader such as cystic fibrosis, allergic bronchopulmonary mycoses (aspergillosis), ciliary dyskinesias, or immune deficiencies.

Other tests, such as allergy testing to assess sensitization to inhalant allergens, help with the management and prognosis of asthma. In a comprehensive U.S. study of 5-12 yr old asthmatic children (Childhood Asthma Management Program [CAMP]), 88% of the subjects had inhalant allergen sensitization according to results of allergy prick skin testing.

**TREATMENT**

The NIH-sponsored National Asthma Education and Prevention Program’s Expert Panel Report 3 (EPR3): Guidelines for the Diagnosis and Management of Asthma 2007 is available online (www.nhlbi.nih.gov/guidelines/asthma/asthgdln.htm). Similar guidelines From the Global Strategy for Asthma Management and Prevention, GINA 2012, are also available online (www.ginaasthma.org). The key components to optimal asthma management are specified (Fig. 144-5). Management of asthma should have the following components: (1) assessment and monitoring of disease activity; (2) education to enhance patient and family knowledge and skills for self-management; (3) identification and management of precipitating factors and comorbid conditions that worsen asthma; and (4) appropriate selection of medications to address the patient’s needs. The long-term goal of asthma management is attainment of optimal asthma control.
Classification of asthma severity and control is based on the domains of **impairment** and **risk**. These domains may not correlate with each other and may respond differently to treatment. In some children with asthma, day-to-day impairment is well controlled, but the risk of severe exacerbations remains. The NIH guidelines have different criteria for 3 childhood age groups—0-4 yr, 5-11 yr, and ≥12 yr—for the evaluation of both severity (Table 144-8) and control (Table 144-9). The level of asthma severity or control is based on the most severe impairment or risk category. In assessing asthma severity, impaired consists of an assessment of the patient's recent symptom frequency (daytime and nighttime, with subtle differences in numeric cutoffs between the 3 age groups). SABA usage for quick relief, ability to engage in normal or desired activities, and airflow compromise are evaluated by spirometry in children 5 yr and older. Risk refers to the likelihood of developing severe asthma exacerbations. Of note, in the absence of frequent symptoms, persistent asthma should be considered, and therefore long-term controller therapy should be initiated for infants or children who have risk factors for asthma (see earlier) and 4 or more episodes of wheezing over the past year that lasted longer than 1 day and affected sleep, or 2 or more exacerbations in 6 mo requiring systemic corticosteroids.

Asthma management can be optimized through regular clinic visits every 2-6 wk until good asthma control is achieved. For children already on controller medication therapy, management is tailored to the child's level of control. The NIH guidelines provide tables for evaluating asthma control for the 3 age groups (see Table 144-9). In evaluation of asthma control, as in severity assessment, impairment includes an assessment of the patient's symptom frequency (daytime and nighttime, SABA usage for quick relief, ability to engage in normal or desired activities, and, for older children, airflow measurements. Furthermore, with respect to risk assessment, besides considering severity and frequency of exacerbations requiring systemic corticosteroids, tracking of lung growth in older children and monitoring adverse effects of medications is also warranted. The degree of impairment and presence of risk are used to determine the patient's level of asthma control as well-controlled, not well-controlled, or very poorly controlled. Children with well-controlled asthma have daytime symptoms ≤2 days/wk and need a rescue bronchodilator ≤2 days/wk; an FEV1 of >80% of predicted (and an FEV1/FVC ratio >80% for children 5-11 yr of age); no interference with normal activity; and <2 exacerbations in the past year. The impairment criteria vary slightly depending on age group: there are different thresholds in the frequency of nighttime awakenings; addition of FEV1/FVC ratio criteria for children 5-11 yr old and addition of validated impairment questionnaires (e.g., Asthma Control Test [ACT] for ages ≥12 yr, Childhood ACT for ages 4-11 yr). Children whose status does not meet all of the criteria defining well-controlled asthma are determined to have either not well-controlled or very poorly controlled asthma, which is determined by the single criterion with the poorest rating.

Two to 4 asthma checkups per year are recommended for reassessing and maintaining good asthma control. Lung function testing (spirometry) is recommended at least annually and more often if asthma is poorly perceived, inadequately controlled and/or lung function is abnormally low. PEF monitoring at home can be helpful in the assessment of asthmatic children with poor symptom perception, other causes of chronic coughing in addition to asthma, moderate to severe asthma, or a history of severe asthma exacerbations. PEF monitoring is feasible in children as young as 4 yr who are able to master this skill. Use of a stoplight zone system tailored to each child's "personal best" PEF values can optimize effectiveness and interest (see Fig 144-3): The green zone (80-100% of personal best) indicates good control; the yellow zone (50-80%) indicates less-than-optimal control and necessary increased awareness and treatment; the red zone (<50%) indicates poor control and greater likelihood of an exacerbation, requiring immediate intervention. In actuality, these ranges are approximate and may need to be adjusted for many asthmatic children by raising the ranges that indicate inadequate control (in the yellow zone, 70-90%). Once-daily PEF monitoring is preferable in the morning when peak flows are typically lower.

**Component 1: Regular Assessment and Monitoring**

Regular assessment and monitoring are based on the concepts of asthma severity, asthma control, and responsiveness to therapy. **Asthma severity** is the intrinsic intensity of disease, and assessment is generally most accurate in patients not receiving controller therapy. Hence, assessing asthma severity directs the initial level of therapy. The 2 general categories are **intermittent** asthma and **persistent** asthma, the latter being further subdivided into **mild**, **moderate**, and **severe**.

In contrast, **asthma control** refers to the degree to which symptoms, ongoing functional impairments, and risk of adverse events are minimized, and goals of therapy are met. In children receiving controller therapy, assessment of asthma control is important in adjusting therapy and is categorized in 3 levels: well-controlled, not well-controlled, and very poorly controlled. **Responsiveness to therapy** is the ease or difficulty with which asthma control is attained by treatment.

![Graph showing PEF levels over time](image-url)
optimal elements—key management.

Effective communications because optimal management depends on their daily assessments and eventually impacting patient outcomes (Table 144-10). Every visit presents an important opportunity to educate the child and family, allowing them to become knowledgeable partners in asthma management, because optimal management depends on their daily assessments and implementation of any management plan. Effective communications take into account sociocultural and ethnic factors of children and their families, provide an open forum for concerns about asthma and its treatment to be raised and addressed, and include patients and families as active participants in the development of treatment goals and selection of medications. Self-management skills should be reevaluated regularly (e.g., inhaler medication technique).

During initial patient visits, a basic understanding of the pathogenesis of asthma (chronic inflammation and AHR underlying a clinically intermittent presentation) can help children with asthma and their parents understand the importance of recommendations aimed at reducing Airways inflammation to achieve and maintain good asthma control. It is helpful to specify the expectations of good asthma control resulting from optimal asthma management (see Fig. 144-5). Addressing concerns about potential adverse effects of asthma pharmacotherapy agents, especially their risks relative to their benefits, is essential in achieving long-term adherence with asthma pharmacotherapy and environmental control measures.

Children with asthma and their families, particularly patients with moderate or severe persistent or poorly controlled asthma and patients who have had severe exacerbations, benefit from a written asthma management plan. This plan has 2 main components: (1) a daily “routine” management plan describing regular asthma medication use and other measures to keep asthma under good control, and (2) an action plan to manage worsening asthma, describing indicators of impending exacerbations, identifying what medications to take, and specifying when and how to contact the regular physician and/or obtain urgent/emergency medical care.

Regular follow-up visits are recommended to help to maintain optimal asthma control. In addition to determining disease control level and revising daily and exacerbation management plans accordingly, follow-up visits are important teaching opportunities to encourage open communication of concerns with asthma management recommendations (e.g., daily administration of controller medications). Reassessing patients’ and parents’ understanding of the role of different medications in asthma management and control, and their technique in using inhaled medications, can be insightful and can help guide teaching to improve adherence to a management plan that might not have been adequately or properly implemented.

**ADHERENCE**

Asthma is a chronic condition that is usually best managed with daily controller medication. However, symptoms wax and wane, severe exacerbations are infrequent, and when asthma is asymptomatic, a natural tendency is to reduce or discontinue daily controller therapies. As such, adherence to a daily controller regimen is commonly suboptimal;

---

**Component 2: Patient Education**

Specific educational elements in the clinical care of children with asthma are believed to make an important difference in home management and in adherence of families to an optimal plan of care and eventually impacting patient outcomes (Table 144-10). Every visit presents an important opportunity to educate the child and family, allowing them to become knowledgeable partners in asthma management, because optimal management depends on their daily assessments and implementation of any management plan. Effective communications take into account sociocultural and ethnic factors of children and their families, provide an open forum for concerns about asthma and its treatment to be raised and addressed, and include patients and families as active participants in the development of treatment goals and selection of medications. Self-management skills should be reevaluated regularly (e.g., inhaler medication technique).

During initial patient visits, a basic understanding of the pathogenesis of asthma (chronic inflammation and AHR underlying a clinically intermittent presentation) can help children with asthma and their parents understand the importance of recommendations aimed at reducing Airways inflammation to achieve and maintain good asthma control. It is helpful to specify the expectations of good asthma control resulting from optimal asthma management (see Fig. 144-5). Addressing concerns about potential adverse effects of asthma pharmacotherapy agents, especially their risks relative to their benefits, is essential in achieving long-term adherence with asthma pharmacotherapy and environmental control measures.

Children with asthma and their families, particularly patients with moderate or severe persistent or poorly controlled asthma and patients who have had severe exacerbations, benefit from a written asthma management plan. This plan has 2 main components: (1) a daily “routine” management plan describing regular asthma medication use and other measures to keep asthma under good control, and (2) an action plan to manage worsening asthma, describing indicators of impending exacerbations, identifying what medications to take, and specifying when and how to contact the regular physician and/or obtain urgent/emergency medical care.

Regular follow-up visits are recommended to help to maintain optimal asthma control. In addition to determining disease control level and revising daily and exacerbation management plans accordingly, follow-up visits are important teaching opportunities to encourage open communication of concerns with asthma management recommendations (e.g., daily administration of controller medications). Reassessing patients’ and parents’ understanding of the role of different medications in asthma management and control, and their technique in using inhaled medications, can be insightful and can help guide teaching to improve adherence to a management plan that might not have been adequately or properly implemented.
inhaled corticosteroids (ICSs) are underused 60% of the time. In one study, children with asthma who required an oral corticosteroid course for an asthma exacerbation had used their daily controller ICS 15% of the time. Misconceptions about controller medication time to onset, efficacy, and safety often underlie poor adherence and can be addressed by asking about such concerns at each visit.

Component 3: Control of Factors Contributing to Asthma Severity

Controllable factors that can worsen asthma can be generally grouped as (1) environmental exposures and (2) comorbid conditions (Table 144-11).

### Eliminating and Reducing Problematic Environmental Exposures

The majority of children with asthma have an allergic component to their disease; steps should be taken to investigate and minimize allergen exposures in sensitized asthmatic patients. The medical history should address potential allergen triggers (see below), but often patients have chronic symptoms and cannot identify potential triggers. Therefore, allergy testing should be considered for at least those with persistent asthma. For asthmatic patients who are allergic to allergens in their homes, reducing or eliminating these home allergen exposures can decrease asthma symptoms, medication requirements, AHR, severe exacerbations, and disease persistence. Common home allergen...

#### RECOMMENDED ACTION FOR TREATMENT

- **Well-Controlled**
  - Maintain current step.
  - Regular follow-up every 1-6 mo to maintain control.
  - Consider step down if well-controlled for at least 3 mo.

- **Not Well-Controlled**
  - Step up<sup>1</sup> (1 step) and reevaluate in 2-6 wk.
  - If no clear benefit in 4-6 wk, consider alternative diagnoses or adjusting therapy.
  - For side effects, consider alternative options.

- **Very Poorly Controlled**
  - Consider short course of oral corticosteroids.
  - Step up<sup>1</sup> (1-2 steps) and reevaluate in 2 wk.
  - If no clear benefit in 4-6 wk, consider alternative diagnoses or adjusting therapy.
  - For side effects, consider alternative options.

---

*Notes:
- The stepwise approach is meant to assist, not replace, the clinical decision making required to meet individual patient needs.
- The level of control is based on the most severe impairment or risk category. Assess impairment domain by caregiver's recall of previous 2-4 wk. Symptom assessment for longer periods should reflect a global assessment such as inquiring whether the patient's asthma is better or worse since the last visit.
- At present, there are inadequate data to correspond frequencies of exacerbations with different levels of asthma control. In general, more frequent and intense exacerbations (e.g., requiring urgent, unscheduled care, hospitalization, or intensive care unit admission) indicate poorer disease control. For treatment purposes, patients who had ≥2 exacerbations requiring oral systemic corticosteroids in the past year may be considered the same as patients who have not-well-controlled asthma, even in the absence of impairment levels consistent with not-well-controlled asthma.
- Validated questionnaires for the impairment domain (the questionnaires do not assess lung function or the risk domain) and definition of minimal important difference (MID) for each:
  - **ATAQ**, Asthma Therapy Assessment Questionnaire; MID = 1.0
  - **ACQ**, Asthma Control Questionnaire; MID = 0.5
  - **ACT**, Asthma Control Test; MID not determined
- **FEV<sub>1</sub>**, forced expiratory volume in 1 sec; **FVC**, forced vital capacity.

---

Control of Factors Contributing to Asthma Severity

Elaborate on the role of environmental factors in asthma severity. Include strategies such as:
- Environmental tobacco smoke elimination or reduction in home and automobiles.
- Allergen exposure elimination or reduction in sensitized asthmatic patients.
- Animal danders: pets (cats, dogs, rodents, birds).
- Pests (mice, rats).
- Dust mites.
- Cockroaches.
- Molds.
- Other airway irritants: wood- or coal-burning smoke.
- Strong chemical odors and perfumes (e.g., household cleaners).
- Dusts.

Treat Comorbid Conditions:
- Rhinitis.
- Sinusitis.
- Gastroesophageal reflux.

Aspirin-exacerbated respiratory disease, formerly called aspirin-induced asthma, is also associated with chronic eosinophilic rhinitis and nasal polyps. Inhibition of cyclooxygenase by aspirin and other nonsteroidal antiinflammatory drugs (including cyclooxygenase [COX]-2 inhibiting agents) is thought to be the primary mechanism, which leads to exacerbations of disease, predominantly in patients with moderate to severe persistent asthma. Accumulation of nasal polyps, a weak COX-1 inhibitor, is safe in low doses, but may produce symptoms if high doses are taken. The incidence is between 5% and 10% of predominantly adolescents with asthma; it is rare in children <10 yr of age. Following ingestion of the drug, symptoms may appear between 30 and 120 min and include profuse rhinorrhea, nasal congestion, and tearing, accompanied by bronchospasm. Vocal cord edema and an anaphylactic-like reaction are rare complications. Aspirin and related drugs should be avoided in these patients; an alternative approach is aspirin desensitization by an allergist.

Treating Comorbid Conditions

Rhinitis, sinusitis, and GER often accompany asthma and worsen disease severity. They can also mimic asthma symptoms and lead to misclassification of asthma severity and control. Indeed, these conditions with asthma are the most common causes of chronic coughing. Effective management of these comorbid conditions may improve asthma symptoms and disease severity, such that less asthma medication is needed to achieve good asthma control.

GER is observed in 43% of children with persistent asthma. GER may worsen asthma through 2 postulated mechanisms: (1) aspiration of refluxed gastric contents (micro- or macro-aspiration); and (2) vagally mediated reflex bronchospasm. Occult GER should be suspected in individuals with difficult-to-control asthma, especially patients who have prominent asthma symptoms while eating or sleeping (in a horizontal position) or who prop themselves up in bed to reduce nocturnal symptoms. GER can be demonstrated by reflux of barium into the esophagus during a barium swallow procedure or by esophageal probe monitoring. Because radiographic studies lack sufficient sensitivity and specificity, extended esophageal monitoring is the method of choice for diagnosing GER. If significant GER is noted, reflux precautions should be instituted (no food 2 hr before bedtime, head of the bed elevated 6 in, avoidance of caffeinated foods and beverages) and medications such as proton pump inhibitors (omeprazole, lansoprazole) or H₂-receptor antagonists (cimetidine, ranitidine) administered for 8-12 wk. Proton pump inhibition did not improve asthma control in a study of children with persistent, poorly controlled asthma and GER.

Rhinitis is usually comorbid with asthma, detected in ≈90% of children with asthma. Rhinitis can be seasonal and/or perennial, with allergic and nonallergic components. Rhinitis complicates and worsens asthma via numerous direct and indirect mechanisms. Nasal breathing may improve asthma and reduce exercise-induced bronchospasm by humidifying and warming inspired air and filtering out allergens and irritants that can trigger asthma and worsen airflow inflammation. Reduction of nasal congestion and obstruction can help the nose to perform these humidifying, warming, and filtering functions. In asthmatic patients, improvement in rhinitis is also associated with improvement in AHR, lower airways inflammation, asthma symptoms, and asthma medication use. Optimal rhinitis management in children is similar to asthma management in regard to the importance of interventions to reduce nasal inflammation (see Chapter 143).

Radiographic evidence for sinus disease is common in patients with asthma. There is usually significant improvement in asthma control in patients diagnosed and treated for sinus disease. A coronal, “screening” or “limited” CT scan of the sinuses is the gold standard test for sinus disease and can be helpful if recurrent sinusitis has been suspected and repeatedly treated without such evidence. In comparison, sinus X-rays are inaccurate. If the patient with asthma has clinical and radiographic evidence for sinusitis, topical therapy to include nasal saline irrigations, intranasal corticosteroids, and a 2-3–wk course of antibiotics should be considered.
Component 4: Principles of Asthma Pharmacotherapy

The current version of NIH asthma guidelines (2007) provides treatment recommendations that vary by age groups and are based on current evidence (Table 144-12). The goals of therapy are to achieve a well-controlled state by reducing the components of both impairment (e.g., preventing chronic and troublesome symptoms, allowing infrequent need of quick-reliever medications, maintaining “normal” lung function, maintaining normal activity levels including physical activity and school attendance, meeting families’ expectations and satisfaction

Each step: Patient education, environmental control, and management of comorbidities.
Age ≥5 yr: Steps 2-4: Consider subcutaneous allergen immunotherapy for patients who have allergic asthma.

QUICK-RELIEF MEDICATION FOR ALL PATIENTS

SABA as needed for symptoms. Intensity of treatment depends on severity of symptoms: up to 3 treatments at 20-min intervals as needed. Short course of oral systemic corticosteroids may be needed.

Caution: Use of SABA >2 days/wk for symptom relief (not prevention of exercise-induced bronchospasm) generally indicates inadequate control and the need to step up treatment.

For ages 0-4 yr: With viral respiratory infection: SABA q4-6h up to 24 hr (longer with physician consult). Consider short course of systemic corticosteroids if exacerbation is severe or patient has history of previous severe exacerbations.

Notes:
- The stepwise approach is meant to assist, not replace, the clinical decision making required to meet individual patient needs.
- If alternative treatment is used and response is inadequate, discontinue it and use the preferred treatment before stepping up.
- If clear benefit is not observed within 4-6 wk and patient/family medication technique and adherence are satisfactory, consider adjusting therapy or alternative diagnosis.
- Studies on children age 0-4 yr are limited. The stepwise approach is meant to assist, not replace, the clinical decision-making required to meet individual patient needs.
- Clinicians who administer immunotherapy or omalizumab should be prepared and equipped to identify and treat anaphylaxis that may occur.
- Theophylline is a less desirable alternative because of the need to monitor serum concentration levels.
- Zileuton is less desirable alternative because of limited studies as adjunctive therapy and the need to monitor liver function.
- Theophylline is a less desirable alternative because of the need to monitor serum concentration levels.
- "LABA, inhaled long-acting β₂-agonist; LTRA, leukotriene receptor antagonist; prn, as needed; SABA, inhaled short-acting β₂-agonist."

with asthma care) and risk (e.g., preventing recurrent exacerbations, reduced lung growth, and medications’ adverse effects). The recommendations for initial therapy are based on assessment of asthma severity. For patients who are already using controller therapy, modification of treatment is based on assessment of asthma control and responsiveness to therapy. A major objective of this approach is to identify and treat all “persistent” and inadequately controlled asthma with antiinflammatory controller medication. Daily controller therapy is not recommended for children with “intermittent asthma.” Management of intermittent asthma is simply the use of a SABA as needed for symptoms and for pretreatment in those with exercise-induced bronchoconstriction (Step 1 therapy; see Table 144-12).

The preferred treatment for all patients with persistent asthma is daily ICS therapy, as monotherapy or in combination with adjunctive therapy. The type(s) and amount(s) of daily controller medications to be used are determined by the asthma severity and control rating. Alternative medications for Step 2 therapy include a leukotriene receptor antagonist (montelukast), nonsteroidal antiinflammatory agents (cromolyn and nedocromil), and theophylline (for youths). For young children (≤5 yr) with moderate or severe persistent asthma, medium-dose ICS monotherapy is recommended (Step 3); combination therapy is recommended only as a Step 4 treatment for uncontrolled asthma.

Along with medium-dose ICSs, combination therapy with an ICS plus any of the following adjunctive therapies (depending on age group) is recommended as Steps 3 and 4 treatment for moderate persistent asthma, or as step-up therapy for uncontrolled persistent asthma: long-acting inhaled β2-agonists (LABAs), leukotriene-modifying agents, chromones, and theophylline. In a study of children with uncontrolled asthma while on low-dose ICS, the addition of LABA provided more improvement than either adding a leukotriene receptor antagonist (LTRA) or increasing ICS dosage. However, some children had a good response to ICS or LTRA, justifying them as step-up controller therapy options.

Children with severe persistent asthma (treatment Steps 5 and 6) should receive high-dose ICS and LABA. Long-term administration of oral corticosteroids as controller therapy can be effective, but is rarely needed with the availability of potent ICS and LABA combination formulations in single devices. In addition, omalizumab can be used in children ≥12 yr old with severe allergic asthma. A rescue course of systemic corticosteroids may be necessary at any step. For children age ≥5 yr with allergic asthma requiring Steps 2-4 care, allergen immunotherapy can be considered.

“Step-Up, Step-Down” Approach

The NIH guidelines emphasize initiating higher-level controller therapy at the outset to establish prompt control, with measures to “step down” therapy once good asthma control is achieved. Initially, airflow limitation and the pathology of asthma may limit the delivery and efficacy of ICS such that stepping up to higher doses and/or combination therapy may be needed to gain asthma control. Furthermore, ICS requires weeks to months of daily administration for optimal efficacy to occur. Combination pharmacotherapy can achieve relatively immediate improvement while also providing daily ICS to improve long-term control and reduce exacerbation risk.

Asthma therapy can be stepped down after good asthma control has been achieved and ICS has had time to achieve optimal efficacy. By determining the lowest number or dose of daily controller medications that can maintain good control, the potential for medication adverse effects is reduced. If a child has had well-controlled asthma for at least 3 mo, the guidelines suggest decreasing the dose or number of the child’s controller medication(s) to establish the minimum required medications to maintain well-controlled asthma. Regular follow-up is still emphasized because the variability of asthma’s course is well recognized. In contrast, if a child has not-well-controlled asthma, the therapy level should be increased by 1 step and close monitoring is recommended. For a child with very poorly controlled asthma, the recommendations are that treatment go up 2 steps and/or a short course of oral corticosteroid therapy be given, with evaluation within 2 wk. As step-up therapy is being considered at any point, it is important to check inhaler technique and adherence, implement environmental control measures, and identify and treat comorbid conditions.

Referral to Asthma Specialist

Referral to an asthma specialist for consultation or co-management is recommended if there are difficulties in achieving or maintaining control. For children younger than 4 yr, referral is recommended for moderate persistent asthma or if the patient requires at least Step 3 care, and should be considered if the patient requires Step 2 care. For children 5 yr of age and older, consultation with a specialist is recommended if the patient requires Step 4 care or higher, and should be considered if Step 3 is required. Referral is also recommended if allergen immunotherapy or anti-immunoglobulin (Ig) E therapy is being considered.

Long-Term Controller Medications

All levels of persistent asthma should be treated with daily medications to improve long-term control (see Table 144-12). Such medications include ICSs, LABAs, leukotriene modifiers, nonsteroidal antiinflammatory agents, and sustained-release theophylline. An anti-IgE preparation, omalizumab (Xolair), is approved by the FDA for use as an add-on therapy in children ≥12 yr who have moderate to severe allergic asthma that is difficult to control. Corticosteroids are the most potent and most effective medications used to treat both the acute (administered systemically) and chronic (administered by inhalation) manifestations of asthma. They are available in inhaled, oral, and parenteral forms (Tables 144-13 and 144-14).

Inhaled Corticosteroids

The NIH guidelines recommend daily ICS therapy as the treatment of choice for all patients with persistent asthma (see Table 144-12). ICS therapy improves lung function as well as reduces asthma symptoms, AHR, and use of “rescue” medications; most importantly, it reduces urgent care visits, hospitalizations, and prednisone use for asthma exacerbations by approximately 50%. ICS therapy may lower the risk of death attributable to asthma. It can achieve all of the goals of asthma management and, as a result, is viewed as first-line treatment for persistent asthma.

Six ICSs are approved for use in children by the FDA, and the NIH guidelines provide an equivalence classification (see Table 144-14), although direct comparisons of efficacy and safety outcomes in children are lacking. ICSs are available in metered-dose inhalers (MDIs), in dry powder inhalers (DPIs), or in suspension for nebulization. Fluticasone propionate, mometasone furoate, ciclesonide, and, to a lesser extent, budesonide are considered “second-generation” ICSs, in that they have greater antiinflammatory potency and diminished systemic bioavailability for potential adverse effects, owing to extensive first-pass hepatic metabolism. The selection of the initial ICS dose is based on the determination of disease severity. A fraction of the initial ICS dose is often sufficient to maintain good control after this goal has been achieved.

Although ICS therapy has been widely used in adults with persistent asthma, its application in children has lagged because of concerns about the potential for adverse effects with long-term use. Generally, clinically significant adverse effects that occur with long-term systemic corticosteroid therapy have not been seen or have only very rarely been reported in children receiving ICSs in recommended doses. The risk of adverse effects from ICS therapy is related to the dose and frequency with which ICSs are given (Table 144-15). High doses (≥2,000 µg/day in children) and frequent administration (4 times/day) are more likely to have local and systemic adverse effects. Children who receive maintenance therapy with higher ICS doses are also likely to require systemic corticosteroid courses for asthma exacerbations, further increasing the risk of corticosteroid adverse effects.

The most commonly encountered adverse effects of ICSs are local: oral candidiasis (thrush) and dysphonia (hoarse voice). Thrush results from propellant-induced mucosal irritation and local immunosuppression. Dysphonia occurs from vocal cord myopathy. These effects are

The potential for growth suppression and osteoporosis with long-term ICS use has been a concern. In the long-term, prospective NIH-sponsored CAMP study of children with mild to moderate asthma, after ~4.3 yr of ICS therapy and 5 yr after the trial, there was a significant 1.7 cm decrease in height in girls, but not in boys. There was also a slight dose-dependent effect of ICS therapy on bone mineral accretion in boys, but not girls. A greater effect on bone mineral accretion was observed with increasing numbers of courses of oral corticosteroid burst therapy for asthma, as well as an increase in risk for osteopenia, again limited to boys. Although this study cannot predict a significant effect of ICS therapy in childhood on osteoporosis in later adulthood, improved asthma control with ICS therapy may result in a need for fewer courses of oral corticosteroid burst therapy over time. These findings were with use of budesonide at doses of about 400 µg/day; higher ICS doses, especially of agents with increased potency, have a greater potential for adverse effects. Hence, corticosteroid adverse effects screening and osteoporosis prevention measures are recommended for patients receiving higher ICS doses, as these patients are also likely to require systemic courses for exacerbations (see Table 144-15).

**Systemic Corticosteroids**

ICS therapy has allowed the large majority of children with asthma to maintain good disease control without maintenance oral corticosteroid therapy. Oral corticosteroids are used primarily to treat asthma exacerbations and, rarely, in patients with severe disease who remain symptomatic despite optimal use of other asthma medications. In these severely asthmatic patients, every attempt should be made to exclude any comorbid conditions and to keep the oral corticosteroid dose at ≤20 mg qod. Doses exceeding this amount are associated with numerous adverse effects (see Chapter 577). To determine the need for continued oral corticosteroid therapy, tapering of the oral corticosteroid

</tr>
</tbody>
</table>

*Risk factors for osteoporosis: Presence of other chronic illness(es), medications (corticosteroids, anticonvulsants, heparin, diuretics), low body weight, family history of osteoporosis, significant fracture history disproportionate to trauma, recurrent falls, impaired vision, low dietary calcium and vitamin D intake, and lifestyle factors (decreased physical activity, smoking, and alcohol intake).

DEXA, dual-energy x-ray absorptiometry; ICS, inhaled corticosteroid; TSH, thyroid-stimulating hormone.
dose (over several weeks to months) should be considered, with close monitoring of the patient's symptoms and lung function.

When administered orally, prednisone, prednisolone, and methylprednisolone are rapidly and completely absorbed, with peak plasma concentrations occurring within 1-2 hr. Prednisone is an inactive prodrug that requires biotransformation via first-pass hepatic metabolism to prednisolone, its active form. Corticosteroids are metabolized in the liver into inactive compounds, with the rate of metabolism influenced by drug interactions and disease states. Anticonvulsants (phenytoin, phenobarbital, carbamazepine) increase the metabolism of prednisolone, methylprednisolone, and dexamethasone, with methylprednisolone most significantly affected. Rifampin also enhances the clearance of corticosteroids and can result in diminished therapeutic effect. Other medications (ketocazole, oral contraceptives) can significantly delay corticosteroid metabolism. Macrolide antibiotics (erythromycin, clarithromycin, troleandomycin) delay the clearance of only methylprednisolone.

Children who require long-term oral corticosteroid therapy are at risk for development of associated adverse effects over time. Essentially all major organ systems can be adversely affected by long-term oral corticosteroid therapy (see Chapter 577). Some of these effects occur immediately (metabolic effects). Others can develop insidiously over several months to years (growth suppression, osteoporosis, cataracts). Most adverse effects occur in a cumulative dose- and duration-dependent manner. Children who require routine or frequent short courses of oral corticosteroids, especially with concurrent high-dose ICSs, should receive corticosteroid adverse effects screening (see Table 144-15) and osteoporosis preventive measures (see Chapter 707).

### Long-Acting Inhaled β-Agonists

LABAs (salmeterol, formoterol) are considered to be daily controller medications, not intended for use as rescue medication for acute asthma symptoms or exacerbations, nor as monotherapy for persistent asthma. Controller formulations that combine an ICS with a LABA (fluticasone/salmeterol, budesonide/formoterol, mometasone/formoterol) are available and recommended, in lieu of separate inhaler delivery devices. Salmeterol has a prolonged onset of action, with maximal bronchodilation approximately 1 hr after administration, whereas formoterol has an onset of action within 5-10 min. Both medications have a prolonged duration of effect, at least 12 hr. Given their long duration of action, they are well suited for patients with nocturnal asthma and for individuals who require frequent SABA use during the day to prevent exercise-induced bronchospasm. Their major role is as an add-on agent in patients whose asthma is suboptimally controlled with ICS therapy alone. For those patients, the addition of a LABA to ICS therapy is superior to doubling the dose of ICS, especially on day and nocturnal symptoms. Of note, the FDA requires all LABA-containing medications to be labeled with a warning of an increase in severe asthma episodes associated with these agents. Some studies have reported a higher number of asthma-related deaths among patients receiving LABA therapy in addition to their usual asthma care than in patients not receiving LABAs. This notice reinforces the appropriate use of LABAs in the management of asthma. Specifically, LABA products should not be initiated as first-line or sole asthma therapy without the concomitant use of an ICS, used with worsening wheezing, or used for acute control of bronchospasm. LABAs should be stopped once asthma control is achieved, and the asthma should be maintained with the use of an asthma controller agent (ICS). Fixed-dose preparations (with an ICS) are recommended to ensure compliance with these guidelines.

### Leukotriene-Modifying Agents

Leukotrienes are potent proinflammatory mediators that can induce bronchospasm, mucus secretion, and airways edema. Two classes of leukotriene modifiers have been developed: inhibitors of leukotriene synthesis and LTRAs. Zileuton, the only leukotriene synthesis inhibitor, is not approved for use in children <12 yr of age. Because zileuton can result in elevated liver function enzyme values in 2-4% of patients, and interacts with medications metabolized via the cytochrome P450 system, it is rarely prescribed for children with asthma.

LTRAs have bronchodilator and targeted antiinflammatory properties and reduce exercise-, aspirin-, and allergen-induced bronchoconstriction. LTRAs are recommended as alternative treatment for mild persistent asthma and as add-on medication with ICS for moderate persistent asthma. Two LTRAs are FDA-approved for use in children: montelukast and zafirlukast. Both medications improve asthma symptoms, decrease the need for rescue β-agonist use, and improve lung function. Montelukast is FDA-approved for use in children ≥1 yr of age and is administered once daily. Zafirlukast is FDA-approved for use in children ≥5 yr of age and is administered twice daily. Although incompletely studied in children with asthma, LTRAs appear to be less effective than ICSs in patients with mild persistent asthma. In general, ICSs improve lung function by 5-15%, whereas LTRAs improve lung function by 2-7.5%. LTRAs are not thought to have significant adverse effects, although case reports described a Churg-Strauss–like vasculitis (pulmonary infiltrates, eosinophilia, cardiomyopathy) in adults with corticosteroid-dependent asthma treated with LTRAs. It remains to be determined whether these patients have a primary eosinophilic vasculitis masquerading as asthma, which was “unmasked” as the oral corticosteroid dose was tapered, or whether the disease is a very rare adverse effect of LTRA. Montelukast has rarely been associated with mood changes and suicidality.

### Nonsteroidal Antiinflammatory Agents

Cromolyn and nedocromil are nonsteroidal antiinflammatory agents that can inhibit allergen-induced asthmatic responses and reduce exercise-induced bronchospasm. Both drugs are considered alternative antiinflammatory drugs for children with mild persistent asthma. Although largely devoid of adverse effects, these medications must be administered frequently (2-4 times/day) and are not nearly as effective as daily controller medications as ICSs and leukotriene-modifying agents. Because they inhibit exercise-induced bronchospasm, they can be used in place of SABAs, especially in children who develop unwanted adverse effects with β-agonist therapy (tremor and elevated heart rate). Cromolyn and nedocromil can also be used in addition to a SABA in a combination pretreatment for exercise-induced bronchospasm in patients who continue to experience symptoms with use of SABA pretreatment alone. Nedocromil has been taken off the market and cromolyn is only available in a solution for nebulization.

### Theophylline

In addition to its bronchodilator effects, theophylline has antiinflammatory properties as a phosphodiesterase inhibitor, although the extent of its clinical relevance has not been clearly established. When used long-term, theophylline can reduce asthma symptoms and the need for rescue SABA use. Although it is considered an alternative monotherapy controller agent for older children and adults with mild persistent asthma, it is no longer considered a first-line agent for young children, in whom there is significant variability in the absorption and metabolism of different theophylline preparations, necessitating frequent dose monitoring (drug blood levels) and adjustments. Because theophylline may have some corticosteroid-sparing effects in individuals with oral corticosteroid–dependent asthma, it is still sometimes used in this group of asthmatic children. Theophylline has a narrow therapeutic window; therefore, when it is used, serum theophylline levels need to be routinely monitored, especially if the patient has a viral illness associated with a fever or is started on a medication known to delay theophylline clearance, such as a macrolide antibiotic, cimetidine, an oral antifungal agent, an oral contraceptive, a leukotriene synthesis inhibitor, or ciprofloxacin. Theophylline overdosage and elevated theophylline levels have been associated with headaches, vomiting, cardiac arrhythmias, seizures, and death.

### Anti–Immunoglobulin E (Omalizumab)

Omalizumab is a humanized monoclonal antibody that binds IgE, thereby preventing its binding to the high-affinity IgE receptor and blocking IgE-mediated allergic responses and inflammation. Because it is unable to bind IgE that is already bound to high-affinity IgE
receptors, the risk of anaphylaxis via direct IgE cross linking by the
drug is circumvented. It is FDA-approved for patients >12 yr old with
moderate to severe asthma, documented hypersensitivity to a peren-
nial allergen, and inadequate disease control with inhaled and/or
oral corticosteroids. Omalizumab is given every 2-4 wk subcutane-
ously, the dosage based on body weight and serum IgE levels. Asth-
matic patients receiving omalizumab have fewer asthma exacerbations
and symptoms while able to reduce their ICS and/or oral corticosteroid
doses. This agent is generally well tolerated, although local injection
site reactions can occur. Hypersensitivity reactions (including anaphy-
laxis) and malignancies have been very rarely associated with omali-
zumab use. The FDA requires packaging of omalizumab to contain a
black box warning of potentially serious and life-threatening anaphy-
lactic reactions with omalizumab treatment. On the basis of reports
from approximately 39,500 patients, anaphylaxis following omali-
lzumab treatment occurred in at least 0.1% of treated people. Although
most of these reactions occurred within 2 hr of omalizumab injection,
there are reports of serious delayed reactions 2-24 hr or even longer
after injections. Anaphylaxis occurred after any omalizumab dose
(including the first dose). Omalizumab-treated patients should be
observed in the facility for an extended period after the drug is given,
and medical providers who administer the injection should be pre-
pared to manage life-threatening anaphylactic reactions. Patients who
receive omalizumab should be fully informed about the signs and
symptoms of anaphylaxis, their chance of development of delayed ana-
phylaxis following each injection, and how to treat it, including the use
of autoinjectable epinephrine.

Mepolizumab, an anti–IL-5 antibody, has been shown to improve
asthma control, reduce prednisone dose and lower sputum and blood
eosinophil events in adults with prednisone-dependent asthma who
also had sputum eosinophils. Dupilumab, an anti–IL-4 receptor anti-
body and another monoclonal antibody against IL-13, have also shown
promise in adult studies.

Quick-Reliever Medications
Quick-reliever or “rescue” medications (SABAs, inhaled anticholiner-
gics, and short-course systemic corticosteroids) are used in the man-
agement of acute asthma symptoms (Table 144-16).

**Short-Acting Inhaled β-Agonists**
Given their rapid onset of action, effectiveness, and 4-6 hr duration of action, SABAs (albuterol, levalbuterol, terbutaline, pirbuterol) are the drugs of choice for acute asthma symptoms (“rescue” medication) and for preventing exercise-induced bronchospasm. β-Agonists cause bronchodilation by inducing airway smooth muscle relaxation, reducing vascular permeability and airways edema, and improving mucociliary clearance. Levalbuterol, or the r-isomer of albuterol, is associated with less tachycardia and tremor, which can be bothersome to some asthmatic patients. Overuse of β-agonists is associated with an increased risk of death or near-death episodes from asthma. This is a major concern for some patients with asthma who rely on the frequent use of SABAs as a “quick fix” for their asthma, rather than using controller medications in a preventive manner. It is helpful to monitor the frequency of SABA use, in that use of at least 1 MDI/mo or at least 3 MDIs/year (200 inhalations/MDI) indicates inadequate asthma control and necessitates improving other aspects of asthma therapy and management.

**Anticholinergic Agents**
As bronchodilators, the anticholinergic agents (ipratropium bromide) are less potent than the β-agonists. Inhaled ipratropium is used primarily in the treatment of acute severe asthma. When used in combination with albuterol, ipratropium can improve lung function and reduce the rate of hospitalization in children who present to the emergency department with acute asthma. Ipratropium is the anticholinergic formulation of choice for children because it has few central nervous system adverse effects and it is available in both MDI and nebulizer formulations. Although widely used in children with asthma exacerbations of all ages, it is approved by the FDA for use in children >12 yr of age. A long-acting inhaled anticholinergic agent, tiotropium, is gaining interest as a potential add-on controller therapy (i.e., in addition to ICS with or without LABA) for adults with asthma.

**Delivery Devices and Inhalation Technique**
Inhaled medications are delivered in aerosolized form in a MDI, as a DPI formulation, or in a suspension or solution form delivered via a
nebulizer. In the past, MDIs, which require coordination and use of a spacer device, have dominated the market. MDIs are now using hydrofluoralkane propellant for its ozone-friendly properties, rather than chlorofluorocarbon. Spacer devices, recommended for the administration of all MDI medications, are simple and inexpensive tools that: (1) decrease the coordination required to use MDIs, especially in young children; (2) improve the delivery of inhaled drug to the lower airways; and (3) minimize the risk of propellant-mediated adverse effects (thrust). Optimal inhalation technique for each puff of MDI-delivered medication is a slow (5 sec) inhalation, then a 5-10 sec breathhold. No waiting time between puffs of medication is needed. Young, preschool-age children cannot perform this inhalation technique. MDI medications can also be delivered with a spacer and mask, using a different technique: Each puff is administered with regular breathing for about 30 sec or 5-10 breaths, a tight seal must be maintained, and talking, coughing, or crying will blow the medication out of the spacer. This technique will not deliver as much medication per puff as the optimal MDI technique used by older children and adults.

DPI devices (e.g., Diskus, Flexhaler Autohaler, Twisthaler, Aerolizer) are popular because of their simplicity of use, albeit adequate inspiratory flow is needed. They are breath-actuated (the drug comes out only as it is breathed in) and spacers are not needed. Mouth rinsing is recommended after ICS use to rinse out ICS deposited on the oral mucosa and reduce the swallowed ICS and the risk of thrush.

Nebulizers have been the mainstay of aerosol treatment for infants and young children. An advantage of using nebulizers is the simple technique required of relaxed breathing. The preferential nasal breathing, small airways, low tidal volume, and high respiratory rate of infants markedly increase the difficulty of inhaled drug therapy targeting the lung airways. Disadvantages of nebulizers include need for a power source, inconvenience in that treatments take about 5 min, expense, and potential for bacterial contamination.

### Asthma Exacerbations and Their Management

Asthma exacerbations are acute or subacute episodes of progressively worsening symptoms and airflow obstruction. Airflow obstruction during exacerbations can become extensive, resulting in life-threatening respiratory insufficiency. Often, asthma exacerbations worsen during sleep (between midnight and 8 A.M.), when airways inflammation and hyperresponsiveness are at their peak. Importantly, SABAs, which are first-line therapy for asthma symptoms and exacerbations, increase pulmonary blood flow through obstructed, unxygenated areas of the lungs with increasing dosage and frequency. When airflow obstruction is not resolved with SABA use, ventilation–perfusion mismatching can cause significant hypoxemia, which can perpetuate bronchoconstriction and further worsen the condition. Severe, progressive asthma exacerbations need to be managed in a medical setting, with administration of supplemental oxygen as first-line therapy and close monitoring for potential worsening. Complications that can occur during severe exacerbations include atelectasis and air leaks in the chest (pneumomediastinum, pneumothorax).

A severe exacerbation of asthma that does not improve with standard therapy is termed status asthmaticus. Immediate management of an asthma exacerbation involves a rapid evaluation of the severity of obstruction and assessment of risk for further clinical deterioration (see Tables 144-15 and 144-16). For most patients, exacerbations improve with frequent bronchodilator treatments and a course of systemic (oral or intravenous) corticosteroid. However, the optimal management of a child with an asthma exacerbation should include a more comprehensive assessment of the events leading up to the exacerbation and the underlying disease severity. Indeed, the frequency and severity of asthma exacerbations help define the severity of a patient’s asthma. Whereas most children who experience life-threatening asthma episodes have moderate to severe asthma by other criteria, some children with asthma appear to have mild disease except when they suffer severe, even near-fatal exacerbations. The biologic, environmental, economic, and psychosocial risk factors associated with asthma morbidity and death can further guide this assessment (Table 144-17).

Asthma exacerbations characteristically vary among individuals but tend to be similar in the same patient. Severe asthma exacerbations, resulting in respiratory distress, hypoxia, hospitalization, and/or respiratory failure, are the best predictors of future life-threatening exacerbations or a fatal asthma episode. In addition to distinguishing such high-risk children, some experience exacerbations that come on over days, with airflow obstruction resulting from progressive inflammation, epithelial sloughing, and cast impaction of small airways. When such a process is extreme, respiratory failure as a result of fatigue can ensue, necessitating mechanical ventilation for numerous days. In contrast, some children experience abrupt-onset exacerbations that may result from extreme AHR and physiologic susceptibility to airways closure. Such exacerbations, when extreme, are asphyxial in nature, often occur outside medical settings, are initially associated with very high arterial partial pressure of carbon dioxide (Paco2) levels, and tend to require only brief periods of supportive ventilation. Recognizing the characteristic differences in asthma exacerbations is important for optimizing their early management.

### Home Management of Asthma Exacerbations

Families of all children with asthma should have a written action plan to guide their recognition and management of exacerbations, along with the necessary medications and tools to manage them. Early recognition of asthma exacerbations in order to intensify treatment early can often prevent further worsening and keep exacerbations from becoming severe. A written home action plan can reduce the risk of asthma death by 70%. The NIH guidelines recommend immediate treatment with “rescue” medication (inhaled SABA, up to 3 treatments in 1 hr). A good response is characterized by resolution of symptoms within 1 hr, no further symptoms over the next 4 hr, and improvement in PEF value to at least 80% of personal best. The child’s physician
In the emergency department, the primary goals of asthma management include correction of hypoxemia, rapid improvement of airflow obstruction, and prevention of progression or recurrence of symptoms. Interventions are based on clinical severity on arrival, response to initial therapy, and presence of risk factors that are associated with asthma morbidity and mortality (see Table 144-17). Indications of a severe exacerbation include breathlessness, dyspnea, retractions, accessory muscle use, tachypnea or labored breathing, cyanosis, mental status changes, a silent chest with poor air exchange, and severe airflow limitation (PEF or FEV₁ value <50% of personal best or predicted values). Initial treatment includes supplemental oxygen, inhaled β-agonist therapy every 20 min for 1 hr, and, if necessary, systemic corticosteroids given either orally or intravenously (see Table 144-16). Inhaled ipratropium may be added to the β-agonist treatment if no significant response is seen with the first inhaled β-agonist treatment. An intramuscular injection of epinephrine or other β-agonist may be administered in severe cases. Oxygen should be administered and continued for at least 20 min after SABA administration to compensate for possible ventilation-perfusion abnormalities caused by SABAs.

Close monitoring of clinical status, hydration, and oxygenation are essential elements of immediate management. A poor response to intensified treatment in the 1st hr suggests that the exacerbation will not remit quickly. The patient may be discharged to home if there is sustained improvement in symptoms, normal physical findings, PEF >70% of predicted or personal best, an oxygen saturation >92% while the patient is breathing room air for 4 hr. Discharge medications include administration of an inhaled β-agonist up to every 3-4 hr plus a 3-7 day course of an oral corticosteroid. Optimizing controller therapy before discharge is also recommended. The addition of ICS to a course of oral corticosteroid in the emergency department setting reduces the risk of exacerbation recurrence over the subsequent month.

Hospital Management of Asthma Exacerbations

For patients with moderate to severe exacerbations that do not adequately improve within 1-2 hr of intensive treatment, observation and/or admission to the hospital, at least overnight, is likely to be needed. Other indications for hospital admission include high-risk features for asthma morbidity or death (see Table 144-17). Admission to an intensive care unit is indicated for patients with severe respiratory distress, poor response to therapy, and concern for potential respiratory failure and arrest.

Supplemental oxygen, frequent or continuous administration of an inhaled bronchodilator, and systemic corticosteroid therapy are the conventional interventions for children admitted to the hospital for status asthmaticus (see Table 144-16). Supplemental oxygen is administered because many children hospitalized with acute asthma have or eventually have hypoxemia, especially at night and with increasing SABA administration. SABAs can be delivered frequently (every 20 min to 1 hr) or continuously (at 5-15 mg/hr). When administered continuously, significant systemic absorption of β-agonist occurs and, as a result, continuous nebulization can obviate the need for intravenous β-agonist therapy. Adverse effects of frequently administered β-agonist therapy include tremor, irritability, tachycardia, and hypokalemia. Patients requiring frequent or continuous nebulized β-agonist therapy should have ongoing cardiac monitoring. Because frequent β-agonist therapy can cause ventilation-perfusion mismatch and hypoxemia, oximetry is also indicated. Inhaled ipratropium bromide is often added to β-agonist therapy every 6 hr if patients do not show a remarkable improvement, although there is little evidence to support its use in hospitalized children receiving aggressive inhaled β-agonist therapy and systemic corticosteroids. In addition to its potential to provide a synergistic effect with a β-agonist agent in relieving severe bronchospasm, ipratropium bromide may be beneficial in patients who have mucous hypersecretion or are receiving β-blockers.

Short-course systemic corticosteroid therapy is recommended for use in moderate to severe asthma exacerbations to hasten recovery and prevent recurrence of symptoms. Corticosteroids are effective as single doses administered in the emergency department, short courses in the clinic setting, and both oral and intravenous formulations in hospitalized children. Studies in children hospitalized with acute asthma have found corticosteroids administered orally to be as effective as intravenous corticosteroids. Accordingly, oral corticosteroid therapy can often be used, although children with sustained respiratory distress who are unable to tolerate oral preparations or liquids are obvious candidates for intravenous corticosteroid therapy.

Patients with persistent severe dyspnea and high-flow oxygen requirements require additional evaluations, such as complete blood cell counts, measurements of arterial blood gases and serum electrolytes, and chest radiograph, to monitor for respiratory insufficiency, comorbidities, infection, and/or dehydration. Hydration status monitoring is especially important in infants and young children, whose increased respiratory rate (insensible losses) and decreased oral intake put them at higher risk for dehydration. Further complicating this situation is the association of increased antidiuretic hormone secretion with status asthmaticus. Administration of fluids at or slightly below maintenance fluid requirements is recommended. Chest physical therapy, incentive spirometry, and mucolytics are not recommended during the early acute period of asthma exacerbations as they can trigger severe bronchoconstriction.

Despite intensive therapy, some asthmatic children remain critically ill and at risk for respiratory failure, intubation, and mechanical ventilation. Complications (air leaks) related to asthma exacerbations increase with intubation and assisted ventilation; every effort should be made to relieve bronchospasm and prevent respiratory failure. Several therapies, including, but not limited to, administered epinephrine, β-agonists, methylxanthines, magnesium sulfate (25-75 mg/kg, maximum dose 2.5 g, given intravenously over 20 min), and inhaled heliox (helium and oxygen mixture) have demonstrated some benefit as adjunctive therapies in patients with severe status asthmaticus. Administration of either methylxanthine or magnesium sulfate requires monitoring of serum levels and cardiovascular status. Parenteral (subcutaneous, intramuscular, or intravenous) epinephrine or terbutaline sulfate may be effective in patients with life-threatening obstruction that is not responding to high doses of inhaled β-agonists, because in such patients, inhaled medication may not reach the lower airway.

Rarely, a severe asthma exacerbation in a child results in respiratory failure, and intubation and mechanical ventilation become necessary. Mechanical ventilation in severe asthma exacerbations requires the careful balance of enough pressure to overcome airways obstruction while reducing hyperinflation, air trapping, and the likelihood of barotrauma (pneumothorax, pneumomediastinum) (see Chapter 411). To minimize the likelihood of such complications, mechanical ventilation should be anticipated, and asthmatic children at risk for the development of respiratory failure should be managed in a pediatric ICU. Elective tracheal intubation with rapid-induction sedatives and paralytic agents is safer than emergency intubation. Mechanical ventilation aims to achieve adequate oxygenation while tolerating mild to
moderate hypercapnia (PCO₂, 50-70 mm Hg) to minimize barotrauma. Volume-cycled ventilators, using short inspiratory and long expiratory times, 10-15 mL/kg tidal volume, 8-15 breaths/min, peak pressures <60 cm H₂O, and without positive end-expiratory pressure are starting mechanical ventilation parameters that can achieve these goals. As measures to relieve mucous plugs, chest percussion and airways lavage are not recommended because they can induce further bronchospasm. One must consider the nature of asthma exacerbations leading to respiratory failure; those of rapid or abrupt onset tend to resolve quickly (hours to 2 days), whereas those that progress gradually to respiratory failure can require days to weeks of mechanical ventilation. Such prolonged cases are further complicated by muscle atrophy and, when combined with corticosteroid-induced myopathy, can lead to severe muscle weakness requiring prolonged rehabilitation. This myopathy should not be confused with the rare occurrence of an asthma-associated flaccid paralysis (Hopkins syndrome), which is of unknown etiology but prolongs the intensive care stay.

In children, management of severe exacerbations in medical centers is usually successful, even when extreme measures are required. Consequently, asthma deaths in children rarely occur in medical centers; most occur at home or in community settings before lifesaving medical care can be administered. This point highlights the importance of home and community management of asthma exacerbations, early intervention measures to keep exacerbations from becoming severe, and steps to reduce asthma severity. A follow-up appointment within 1-2 wk of a child’s discharge from the hospital after resolution of an asthma exacerbation should be used to monitor clinical improvement and to reinforce key educational elements, including action plans and controller medications.

Special Management Circumstances

Management of Infants and Young Children. Recurrent wheezing episodes in preschool-age children are very common, occurring in as much as one-third of this population. Of them, most improve and even become asymptomatic during the prepubescent school-age years, whereas others have lifelong persistent asthma. All require management of their recurrent wheezing problems (see Tables 144-5, 144-7, and 144-12). The updated NIH guidelines recommend risk assessment to identify preschool-age children who are likely to have persistent asthma. One implication of this recommendation is that these at-risk children may be candidates for conventional asthma management, including daily controller therapy and early intervention with exacerbations (see Tables 144-8, 144-9, and 144-12). Nebulized budesonide and montelukast appear to be more effective than cromolyn. For young children with a history of moderate to severe exacerbations, nebulized budesonide is FDA approved, and its use as a controller medication could prevent subsequent exacerbations.

Using aerosol therapy in infants and young children with asthma presents unique challenges. There are 2 delivery systems for inhaled medications for this age group, the nebulizer and the MDI with spacer/holding chamber and face mask. Multiple studies demonstrate the effectiveness of both nebulized albuterol in acute episodes and neb-

Asthma Management in Pregnancy. The goals of asthma management during pregnancy should include prevention of exacerbations and control of chronic symptoms through the use of medications that pose minimal risk to the mother and fetus because most drugs cross the placenta. It is considered safer for pregnant asthmatic women to be treated with controller medications than it is to have uncontrolled symptoms and severe exacerbations. Albuterol is the preferred SABA for use during pregnancy. There is reassuring efficacy and safety data from prospective cohort studies supporting ICS use in pregnant women with asthma. Budesonide is currently the preferred ICS for pregnant women, attaining an FDA Pregnancy Category B rating because of substantial reassuring safety data. Nonmedication approaches to improve asthma control are encouraged. A multidisciplinary approach with monthly evaluations (including pulmonary function tests when not contraindicated) and ongoing consultation with the obstetrician and asthma specialist is recommended. Frequent fetal and maternal surveillance is especially important for adolescents with suboptimal asthma control, those with moderate to severe asthma, and those with a recent exacerbation.

Asthma Management During Surgery. Patients with asthma are at risk from disease-related complications from surgery, such as bronchoconstriction and asthma exacerbation, atelectasis, impaired coughing, respiratory infection, and latex exposure, that may induce asthma complications in patients with latex allergy. All patients with asthma should be evaluated before surgery, and those who are inadequately controlled should allow time for intensified treatment in order to improve asthma stability before surgery if possible. A systemic corticosteroid course may be indicated for the patient who is having symptoms and/or FEV₁ or PEF values <80% of the patient's personal best. In addition, patients who have received >2 wk of systemic corticosteroid and/or moderate- to high-dose ICS therapy may be at risk for intraoperative adrenal insufficiency. For these patients, anesthesia services should be alerted to provide "stress" replacement doses of systemic corticosteroid for the surgical procedure and possibly the postoperative period if needed.

PROGNOSIS

Recurrence coughing and wheezing occurs in 35% of preschool-age children. Of these, approximately one-third continue to have persistent asthma into later childhood, and approximately two-thirds improve on their own through their teen years. Asthma severity by the ages of 7-10 yr is predictive of asthma persistence in adulthood. Children with moderate to severe asthma and with lower lung function measures are likely to have persistent asthma as adults. Children with milder asthma and normal lung function are likely to improve over time, with some becoming periodically asthmatic (disease-free for months to years); however, complete remission for 5 yr in childhood is uncommon.

PREVENTION

Although chronic airways inflammation may result in pathologic remodeling of lung airways, conventional anti-inflammatory interventions—the cornerstone of asthma control—do not help children outgrow their asthma. Although controller medications reduce asthma morbidities, most children with moderate to severe asthma continue to have symptoms into young adulthood. Investigations into the environmental and lifestyle factors responsible for the lower prevalence of childhood asthma in rural areas and farming communities suggest that early immunomodulatory intervention might prevent asthma development. A hygiene hypothesis purports that naturally occurring microbial exposures in early life might drive early immune development away from allergic sensitization, persistent airways inflammation, and remodeling. If these natural microbial exposures truly have an asthma-protective effect, without significant adverse health consequences, then these findings may foster new strategies for asthma prevention.

Several nonpharmacotherapeutic measures with numerous positive health attributes—avoidance of environmental tobacco smoke (beginning prenatally), prolonged breastfeeding (>4 mo), an active lifestyle, and a healthy diet—might reduce the likelihood of asthma development. Immunizations are currently not considered to increase the likelihood of development of asthma; therefore, all standard childhood immunizations are recommended for children with asthma, including varicella and annual influenza vaccines.

Bibliography is available at Expert Consult.
Atopic dermatitis (AD), or eczema, is the most common chronic relapsing skin disease seen in infancy and childhood. It affects 10-30% of children worldwide and frequently occurs in families with other atopic diseases, such as asthma, allergic rhinitis, and food allergy. Infants with AD are predisposed to development of allergic rhinitis and/or asthma later in childhood, a process called "the atopic march."

**ETIOLOGY**
AD is a complex genetic disorder that results in a defective skin barrier, reduced skin innate immune responses, and exaggerated T-cell responses to environmental allergens and microbes that lead to chronic skin inflammation.

**PATHOLOGY**
Acute AD skin lesions are characterized by spongiosis, or marked intercellular edema, of the epidermis. In AD, dendritic antigen-presenting cells in the epidermis, such as Langerhans cells, exhibit surface-bound immunoglobulin (Ig) E molecules. These antigen-presenting cells play an important role in cutaneous allergen presentation to T-helper type 2 (Th2) cells (see Chapter 140). There is a marked perivascular T-cell infiltrate with occasional monocyte-macrophages in acute AD lesions. Mast cells are found in normal numbers but in different stages of degranulation. Chronic, lichenified AD is characterized by a hyperplastic epidermis with hyperkeratosis, and minimal spongiosis. There are predominantly IgE-bearing Langerhans cells in the epidermis, and macrophages in the dermal mononuclear cell infiltrate. Mast cell and eosinophil numbers are increased, contributing to skin inflammation.

**PATHOGENESIS**
Two forms of AD have been identified. Atopic eczema is associated with IgE-mediated sensitization (at onset or during the course of eczema) and occurs in 70-80% of patients with AD. Nonatopic eczema is not associated with IgE-mediated sensitization and is seen in 20-30% of patients with AD. Both forms of AD are associated with eosinophilia. In atopic eczema, circulating T cells expressing the skin homing receptor cutaneous lymphocyte-associated antigen produce increased levels of Th2 cytokines, including interleukin (IL)-4 and IL-13, which induce isotype switching to IgE synthesis. Another cytokine, IL-5, plays an important role in eosinophil development and survival. Nonatopic eczema is associated with lower IL-4 and IL-13 production than is atopic eczema.

Compared with the skin of healthy subjects, both unaffected skin and acute skin lesions of patients with AD have an increased number of cells expressing IL-4 and IL-13. Chronic AD skin lesions, by contrast, have significantly fewer cells that express IL-4 and IL-13, but many more cells expressing IL-5, granulocyte-macrophage colony-stimulating factor, IL-12, and interferon (IFN)–γ than acute AD lesions. Chronic AD is characterized by a shift from a Th2-dominant to a Th1-dominant profile. The infiltration of IL-22–expressing T cells correlates with severity of AD, blocks keratinocyte differentiation, and induces epidermal hyperplasia.

The development of AD skin lesions is orchestrated by local tissue expression of proinflammatory cytokines and chemokines, which play a central role in defining the nature of the inflammatory infiltrate in AD. The chemotactic protein, CCL27, is highly upregulated in AD and preferentially attracts cutaneous lymphocyte-associated antigen-positive T cells to the skin. Other C-C chemokines, RANTES (regulated on activation, normal T-cell expressed and secreted), monocyte chemotactic protein-4, and eotaxin are increased in AD skin lesions, resulting in chemotaxis of eosinophils, macrophages, and Th2 lymphocytes expressing their receptor (CCR3).

In healthy people, the skin acts as a protective barrier against external irritants, moisture loss, and infection. Proper function of the skin depends on adequate moisture and lipid content, functional immune responses, and structural integrity. Severely dry skin is a hallmark of AD. This results from compromise of the epidermal barrier, which leads to excess transepidermal water loss, allergen penetration, and microbial colonization. Filaggrin, a structural protein in the epidermis, and its breakdown products are critical to skin barrier function. Genetic mutations in the filaggrin gene family have been identified in up to 50% of patients with severe AD. Cytokines found in allergic inflammation, such as IL-4, IL-13, IL-22, IL-25, and tumor necrosis factor, can also reduce filaggrin expression. AD patients thereby have increased risk of bacterial, viral, and fungal infection related to impairment of innate immunity, including a loss of barrier function and impaired generation of antimicrobial peptides.

**CLINICAL MANIFESTATIONS**
AD typically begins in infancy. Approximately 50% of patients experience symptoms in the 1st yr of life, and an additional 30% are diagnosed between 1 and 5 yr of age. Intense pruritus, especially at night, and cutaneous reactivity are the cardinal features of AD. Scratching and excoriation cause increased skin inflammation that contributes to the development of more pronounced eczematous skin lesions. Foods (cow milk, egg, peanut, tree nuts, soy, wheat, fish, shellfish), aeroallergens (pollen, grass, animal dander, dust mites), infection (staphylococcus, herpes simplex, molluscum), reduced humidity, excessive sweating, and irritants (wool, acrylic, soaps, toiletries, fragrances, detergents) can exacerbate (trigger) pruritus and scratching.

Acute AD skin lesions are intensely pruritic with erythematosus papules (Figs. 145-1 and 145-2). Subacute dermatitis manifests as erythematous, excoriated, scaling papules. In contrast, chronic AD is characterized by lichenification (Fig. 145-3), or thickening of the skin with accentuated surface markings, and fibrotic papules. In chronic AD, all
Clinical Features of Atopic Dermatitis

AD is diagnosed on the basis of 3 major features: pruritus, an eczematous dermatitis that fits into a typical presentation, and a chronic or chronically relapsing course (Table 145-1). Associated features, such as a family history of asthma, hay fever, elevated IgE, and immediate skin test reactivity, are variably present.

Many inflammatory skin diseases, immunodeficiencies, skin malignancies, genetic disorders, infectious diseases, and infestations share symptoms with AD and should be considered and excluded before a diagnosis of AD is established (Table 145-2). Severe combined immunodeficiency syndrome (see Chapter 126.1) should be considered for infants presenting in the 1st yr of life with diarrhea, failure to thrive, generalized scaling rash, and recurrent cutaneous and/or systemic infection. Histiocytosis (see Chapter 507) should be excluded in any infant with AD and failure to thrive. Wiskott-Aldrich syndrome (see Chapter 126.2), an X-linked recessive disorder associated with thrombocytopenia, immune defects, and recurrent severe bacterial infections, is characterized by a rash almost indistinguishable from that in AD. One of the hyper-IgE syndromes (see Chapter 126.2) is characterized by markedly elevated serum IgE values, recurrent deep-seated bacterial infections, chronic dermatitis, and refractory dermatophytosis. Many of these patients have disease as a result of autosomal dominant STAT3 mutations. In contrast, some patients with hyper-IgE syndrome present with increased susceptibility to viral infections and an autosomal recessive pattern of disease inheritance. These patients may have a Dock 8 (Dedicator of cytokinesis 8) mutation. This diagnosis should be considered in young children with severe eczema, food allergy, and disseminated skin viral infections.

Adolescents who present with an eczematous dermatitis but no history of childhood eczema, respiratory allergy, or atopic family history may have allergic contact dermatitis (see Chapter 655.1). A contact allergen may be the problem in any patient whose AD does not respond to appropriate therapy. Sensitizing chemicals, such as parabens and lanolin, can be irritants for patients with AD and are commonly found as vehicles in therapeutic topical agents. Topical glucocorticoid contact allergy has been reported in patients with chronic dermatitis on topical corticosteroid therapy. Eczematous dermatitis has also been reported with HIV infection as well as with a variety of infestations such as scabies. Other conditions that can be confused with AD include psoriasis, ichthyoses, and seborrheic dermatitis.

3 types of skin reactions may coexist in the same individual. Most patients with AD have dry, lackluster skin irrespective of their stage of illness. Skin reaction pattern and distribution vary with the patient’s age and disease activity. AD is generally more acute in infancy and involves the face, scalp, and extensor surfaces of the extremities. The diaper area is usually spared. Older children and children with chronic AD have lichenification and localization of the rash to the flexural folds of the extremities. AD often goes into remission as the patient grows older, leaving an adolescent or adult with skin prone to itching and inflammation when exposed to exogenous irritants.

LABORATORY FINDINGS

There are no specific laboratory tests to diagnose AD. Many patients have peripheral blood eosinophilia and increased serum IgE levels. Serum IgE measurement or prick skin testing can identify the allergens to which patients are sensitized. The diagnosis of clinical allergy to these allergens requires confirmation by history and environmental challenges.

**TREATMENT**

The treatment of AD requires a systematic, multifaceted approach that incorporates skin hydration, topical anti-inflammatory therapy, identification and elimination of flare factors (Table 145-3), and, if necessary, systemic therapy. Assessment of the severity also helps direct therapy (Table 145-4).

**Cutaneous Hydration**

Because patients with AD have impaired skin barrier function from reduced lipid levels, they present with diffuse, abnormally dry skin, or xerosis. *Moisturizers are first-line therapy.* Lukewarm soaking baths for 15-20 min followed by the application of an occlusive emollient to retain moisture provide symptomatic relief. Hydrophilic ointments of varying degrees of viscosity can be used according to the patient’s preference. Occlusive ointments are sometimes not well tolerated because of interference with the function of the eccrine sweat ducts and may induce the development of folliculitis. In these cases, less occlusive agents should be used. Several prescription (classified as a medical device) “therapeutic moisturizers/barrier creams” are available, containing components such as ceramides and filaggrin acid metabolites intended to improve skin barrier function. There are little data demonstrating their efficacy over standard emollients.

Hydration by baths or wet dressings promotes transepidermal penetration of topical glucocorticoids. Dressings may also serve as effective barriers against persistent scratching, in turn promoting healing of excoriated lesions. Wet dressings are recommended for use on severely affected or chronically involved areas of dermatitis refractory to skin care. It is critical that wet dressing therapy be followed by topical emollient application to avoid potential drying and fissuring from the therapy. Wet dressing therapy can be complicated by maceration and secondary infection and should be closely monitored by a physician.

**Topical Corticosteroids**

*Topical corticosteroids are the cornerstone of antinflammatory treatment for acute exacerbations of AD.* Patients should be carefully instructed on their use of topical glucocorticoids in order to avoid potential adverse effects. There are 7 classes of topical glucocorticoids, ranked according to their potency as determined by vasoconstrictor assays (Table 145-5). Because of their potential adverse effects, the...

*Representative corticosteroids are listed by group from 1 (superpotent) through 9 (least potent).

Topical Calcineurin Inhibitors

The nonsteroidal topical calcineurin inhibitors are effective in reducing AD skin inflammation. Pimecrolimus cream 1% (Elidel) is indicated for mild to moderate AD. Tacrolimus ointment 0.1% and 0.03% (Protopic) is indicated for moderate to severe AD. Both are approved for short-term or intermittent long-term treatment of AD in patients ≥2 yr whose disease is unresponsive to or who are intolerant of other conventional therapies or for whom these therapies are inadvisable owing to potential risks. Topical calcineurin inhibitors may be better than topical corticosteroids in the treatment of patients whose AD is poorly responsive to topical steroids, of patients with steroid phobia, and of patients with face and neck dermatitis, in which ineffective, low-potency topical corticosteroids are usually used because of fears of steroid-induced skin atrophy.

Tar Preparations

Coal tar preparations have antipruritic and antiinflammatory effects on the skin; however, the antiinflammatory effects are usually not as pronounced as those of topical glucocorticoids or calcineurin inhibitors. Tar preparations are useful in reducing the potency of topical glucocorticoids required in long-term maintenance therapy of AD. Tar shampoos can be particularly beneficial for scalp dermatitis. Adverse effects associated with tar preparations include skin irritation, folliculitis, and photosensitivity.

Antihistamines

Systemic antihistamines act primarily by blocking the histamine H1 receptors in the dermis, thereby reducing histamine-induced pruritus. Histamine is only one of many mediators that induce pruritus of the skin, so patients may derive minimal benefit from antihistaminic therapy. Because pruritus is usually worse at night, sedating antihistamines (hydroxyzine, diphenhydramine) may offer an advantage with their soporific side effects when used at bedtime. Doxepin hydrochloride has both tricyclic antidepressant and H1- and H2-receptor blocking effects. Short-term use of a sedative to allow adequate rest may be appropriate in cases of severe nocturnal pruritus. Studies of newer nonsedating antihistamines have shown variable effectiveness in controlling pruritus in AD, although they may be useful in the small subset of patients with AD and concomitant urticaria.

Systemic Corticosteroids

Systemic corticosteroids are rarely indicated in the treatment of chronic AD. The dramatic clinical improvement that may occur with systemic corticosteroids is frequently associated with a severe rebound flare of AD after therapy discontinuation. Short courses of oral corticosteroids may be appropriate for an acute exacerbation of AD while other treatment measures are being instituted in parallel. If a short course of oral corticosteroids is given, it is important to taper the dosage and begin intensified skin care, particularly with topical corticosteroids and frequent bathing followed by application of emollients, to prevent rebound flaring of AD.

Cyclosporine

Cyclosporine is a potent immunosuppressive drug that acts primarily on T cells by suppressing cytokine gene transcription. Cyclosporine forms a complex with an intracellular protein, cyclophilin, and this complex, in turn, inhibits calcineurin, a phosphatase required for...
activation of NFAT (nuclear factor of activated T cells), a transcription factor necessary for cytokine gene transcription. Cyclosporine (5 mg/kg/day) for short-term and long-term (1 yr) use has been beneficial for children with severe, refractory AD. Possible adverse effects include renal impairment and hypertension.

**Antimetabolites**
Myco phenolate mofetil is a purine biosynthesis inhibitor used as an immunosuppressant in organ transplantation that has been used for treatment of refractory AD. Aside from immunosuppression, herpes simples reinitis and dose-related bone marrow suppression have been reported with its use. Of note, not all patients benefit from treatment. Therefore, the medication should be discontinued if the disease does not respond within 4-8 wk. Methotrexate is an antimetabolite with potent inhibitory effects on inflammatory cytokine synthesis and cell chemotaxis. Methotrexate has been used for patients with recalcitrant AD. In AD, dosing is more frequent than the weekly dosing used for psoriasis. Azathioprine is a purine analog with antiinflammatory and antiproliferative effects that has been used for severe AD. Myelosuppression is a significant adverse effect, and thiopurine methyl transferase levels may identify individuals at risk for it. Before any of these drugs is used, patients should be referred to an AD specialist who is familiar with treatment of severe AD to weigh relative benefits of alternative therapies.

**Phototherapy**
Natural sunlight is often beneficial to patients with AD as long as sunburn and excessive sweating are avoided. Many phototherapy modalities are effective for AD, including ultraviolet A-1, ultraviolet B, narrow-band ultraviolet B, and psoralen plus ultraviolet A. Phototherapy is generally reserved for patients in whom standard treatments fail. Maintenance treatments are usually required for phototherapy to be effective. Short-term adverse effects with phototherapy include erythema, skin pain, pruritus, and pigmentation. Long-term adverse effects include predisposition to cutaneous malignancies.

**Unproven Therapies**
Other therapies that may be considered in patients with refractory AD are as follows.

**Interferon-γ**
IFN-γ is known to suppress Th2-cell function. Several studies, including a multicenter, double-blind, placebo-controlled trial and several open trials, have demonstrated that treatment with recombinant human IFN-γ results in clinical improvement of AD. Reduction in clinical severity of AD correlated with the ability of IFN-γ to decrease total circulating eosinophil counts. Influenza-like symptoms are commonly observed side effects during the treatment course.

**Omalizumab**
Treatment of patients who have severe AD and elevated serum IgE values with monoclonal anti-IgE may be considered in those with allergen-induced flares of AD. However, there have been no published double-blind, placebo-controlled trials of its use. Most reports have been case studies and show inconsistent responses to anti-IgE.

**Allergen Immunotherapy**
In contrast to its acceptance for treatment of allergic rhinitis and extrinsic asthma, immunotherapy with allergens in the treatment of AD is controversial. There are reports of both disease exacerbation and improvement. Studies suggest specific immunotherapy in patients with AD sensitized to dust mite allergen showed improvement in severity of skin disease, as well as reduction in topical steroid use.

**Probiotics**
Perinatal administration of the probiotic *Lactobacillus rhamnosus* strain GG has been shown to reduce the incidence of AD in at-risk children during the first 2 yr of life. The treatment response has been found to be more pronounced in patients with positive skin prick test results and elevated IgE values. Other studies have not demonstrated a benefit.

### Chinese Herbal Medications
Several placebo-controlled clinical trials have suggested that patients with severe AD may benefit from treatment with traditional Chinese herbal therapy. The subjects had significantly reduced skin disease and decreased pruritus. The beneficial response of Chinese herbal therapy is often temporary, and effectiveness may wear off despite continued treatment. The possibility of hepatic toxicity, cardiac side effects, or idiosyncratic reactions remains a concern. The specific ingredients of the herbs also remain to be elucidated, and some preparations have been found to be contaminated with corticosteroids. At present, Chinese herbal therapy for AD is considered investigational.

**Vitamin D**
Vitamin D deficiency often accompanies severe AD. Vitamin D enhances skin barrier function, reduces corticosteroid requirements to control inflammation and augments skin antimicrobial function. Several small clinical studies suggest vitamin D can enhance antimicrobial peptide expression in the skin and reduce severity of skin disease especially in patients with low baseline vitamin D, for example, during the wintertime when exacerbation of AD often occurs. Patients with AD might benefit from supplementation with vitamin D, particularly if they have a documented low level or low vitamin D intake.

### AVOIDING TRIGGERS
It is essential to identify and eliminate triggering factors, both during the period of acute symptoms and on a long-term basis to prevent recurrences (see Table 145-3).

**Irritants**
Patients with AD have a low threshold response to irritants that trigger their itch-scratch cycle. Soaps or detergents, chemicals, smoke, abrasive clothing, and exposure to extremes of temperature and humidity are common triggers. Patients with AD should use soaps with minimal defatting properties and a neutral pH. New clothing should be laundered before wearing to decrease levels of formaldehyde and other chemicals. Residual laundry detergent in clothing may trigger the itch-scratch cycle; using a liquid rather than powder detergent and adding a second rinse cycle facilitates removal of the detergent.

Every attempt should be made to allow children with AD to be as normally active as possible. A sport such as swimming may be better tolerated than others that involve intense perspiration, physical contact, or heavy clothing and equipment. Rinsing off chlorine immediately and lubricating the skin after swimming are important. Although ultraviolet light may be beneficial to some patients with AD, high sun protection factor sunscreens should be used to avoid sunburn.

**Foods**
Food allergy is comorbid in approximately 40% of infants and young children with moderate to severe AD (see Chapter 151). Undiagnosed food allergies in patients with AD may induce eczematous dermatitis in some patients and urticarial reactions, wheezing, or nasal congestion in others. Increased severity of AD symptoms and younger age correlate directly with the presence of food allergy. Removal of food allergens from the diet leads to significant clinical improvement but requires a great deal of education, because most common allergens (egg, milk, peanut, wheat, soy) contaminate many foods and are difficult to avoid.

Although ultraviolet light may be beneficial to some patients with AD, high sun protection factor sunscreens should be used to avoid sunburn.

Potential allergens can be identified by a careful history and performing selective skin prick tests or in vitro blood testing for allergen-specific IgE. Negative skin and blood test results for allergen-specific IgE have a high predictive value for excluding suspected allergens. Positive results of skin or blood tests using foods often do not correlate with clinical symptoms and should be confirmed with controlled food challenges and elimination diets. Extensive elimination diets, which can be nutritionally deficient, are rarely required. Even with multiple
positive skin test results, the majority of patients react to fewer than 3 foods under controlled challenge conditions.

**Aeroallergens**
In older children, AD flares can occur after intranasal or epicutaneous exposure to aeroallergens such as fungi, animal dander, grass, and ragweed pollen. Avoiding aeroallergens, particularly dust mites, can result in clinical improvement of AD. Avoidance measures for dust mite–allergic patients include using dust mite–proof encasings on pillows, mattresses, and box springs; washing bedding in hot water weekly; removing bedroom carpeting; and decreasing indoor humidity levels with air conditioning.

**Infections**
Patients with AD have increased susceptibility to bacterial, viral, and fungal skin infections. Antistaphylococcal antibiotics are very helpful for treating patients who are heavily colonized or infected with *Staphylococcus aureus*. Erythromycin and azithromycin are usually beneficial for patients who are not colonized with a resistant *S. aureus* strain; a first-generation cephalosporin (cephalexin) is recommended for macrolide-resistant *S. aureus*. Topical mupirocin is useful in the treatment of localized impetiginous lesions, with systemic antibiotics for widespread infections. Cytokine-mediated skin inflammation contributes to skin colonization with *S. aureus*; this fact indicates the importance of combining effective anti-inflammatory therapy with antibiotics for treating moderate to severe AD to avoid the need for repeated courses of antibiotics, which can lead to the emergence of antibiotic-resistant strains of *S. aureus*. Dilute bleach baths (*1/2* cup of bleach in 40 gallons of water) twice weekly may be also considered to reduce *S. aureus* colonization. In one randomized trial the group who received the bleach baths plus intranasal mupirocin (5 days/mo) had significantly decreased severity of AD at 1 and 3 mo compared with placebo. Patients rinse off after the soaking. Further studies are needed to validate this technique.

Herpes simplex virus (HSV) can provoke recurrent dermatitis and may be misdiagnosed as *S. aureus* infection. The presence of punched-out erosions, vesicles, and infected skin lesions that fail to respond to oral antibiotics suggests HSV infection, which can be diagnosed by a Giemsa-stained Tzanck smear of cells scraped from the vesicle base or by viral polymerase chain reaction or culture. Topical corticosteroids should be temporarily discontinued if HSV infection is suspected. Reports of life-threatening dissemination of HSV infections in patients with AD who have widespread disease mandate antiviral treatment. Persons with AD are also susceptible to *eczema vaccinatum*, which is similar in appearance to eczema herpeticum and historically follows smallpox (vaccinia virus) vaccination. Cutaneous warts and molluscum contagiosum are additional viral infections affecting children with AD. Dermatomyositis infections also can contribute to exacerbation of AD. Patients with AD have been found to have a greater susceptibility to *Trichophyton rubrum* fungal infections than nonatopic control subjects. There has been particular interest in the role of *Malassezia furfur* (formerly known as *Pityrosporum ovale*) in AD because it is a lipophilic yeast commonly present in the seborrheic areas of the skin. IgE antibodies against *M. furfur* have been found in patients with head and neck dermatitis. A reduction of AD severity has been observed in those patients after treatment with antifungal agents.

**COMPLICATIONS**
Exfoliative dermatitis may develop in patients with extensive skin involvement. It is associated with generalized redness, scaling, weeping, crusting, systemic toxicity, lymphadenopathy, and fever, and is usually caused by superinfection (e.g., with toxin-producing *S. aureus* or HSV infection) or inappropriate therapy. In some cases, the withdrawal of systemic glucocorticoids used to control severe AD precipitates exfoliative erythroderma.

Eyelid dermatitis and chronic blepharitis may result in visual impairment from corneal scarring. **Atopic keratoconjunctivitis** is usually bilateral and can have disabling symptoms that include itching, burning, tearing, and copious mucoid discharge. Vernal conjunctivitis is associated with papillary hypertrophy or cobblestoning of the upper eyelid conjunctiva. It typically occurs in younger patients and has a marked seasonal incidence with spring exacerbations. **Keratoconus** is a conical deformity of the cornea believed to result from chronic rubbing of the eyes in patients with AD. Cataracts may be a primary manifestation of AD or from extensive use of systemic and topical glucocorticoids, particularly around the eyes.

**PROGNOSIS**
AD generally tends to be more severe and persistent in young children, particularly if they have null mutations in their filaggrin genes. Periods of remission occur more frequently as patients grow older. Spontaneous resolution of AD has been reported to occur after age 5 yr in 40-60% of patients affected during infancy, particularly for mild disease. Earlier studies suggested that approximately 84% of children outgrow their AD by adolescence; however, later studies reported that AD resolves in approximately 20% of children monitored from infancy until adolescence and becomes less severe in 65%. Of those adolescents treated for mild dermatitis, >50% may experience a relapse of disease as adults, which frequently manifests as hand dermatitis, especially if daily activities require repeated hand wetting. Predictive factors of a poor prognosis for AD include widespread AD in childhood, filaggrin gene null mutations, concomitant allergic rhinitis and asthma, family history of AD in parents or siblings, early age at onset of AD, being an only child, and very high serum IgE levels.

**PREVENTION**
Breastfeeding or a feeding with a hypoallergenic hydrolyzed formula may be beneficial. Probiotics and prebiotics may also reduce the incidence or severity of AD, but this approach is unproven. If an infant with AD is diagnosed with food allergy, the breast feeding mother may need to eliminate the implicated food allergen from her diet. Identification and elimination of triggering factors is the mainstay for prevention of flares as well as for the long-term treatment of AD.

Emollient therapy applied to the whole body for the first few months of life may enhance the cutaneous barrier and reduce the risk of eczema.

*Bibliography is available at Expert Consult.*
Atopic Dermatitis (Atopic Eczema)

Allergic responses to stinging or, more rarely, biting insects vary from localized cutaneous reactions to systemic anaphylaxis. Allergic reactions that are caused by inhalation of airborne particles of insect origin result in acute and chronic respiratory symptoms of seasonal or perennial rhinitis, conjunctivitis, and/or asthma.

ETIOLOGY
Most reactions to stinging and biting insects, such as those induced by wasps, mosquitoes, flies, and fleas, are limited to a primary lesion isolated to the area of the sting or bite and do not represent an allergic response. Occasionally, insect stings or bites induce pronounced localized reactions or systemic reactions that may be based on immediate or delayed hypersensitivity reactions. Systemic allergic responses to insects are attributed most typically to immunoglobulin (Ig) E antibody–mediated responses, which are caused primarily by stings from venomous insects of the order Hymenoptera and more rarely from ticks, spiders, scorpions, and *Triatoma* (kissing bug). Members of the order Hymenoptera include apids (honeybee, bumblebee), vespids
Hymenoptera venoms contain numerous components with toxic and pharmacologic activity and with allergenic potential. These constituents include vasoactive substances such as histamine, acetylcholine, and kinins; enzymes such as phospholipase and hyaluronidase; apamin; melittin; and formic acid. The majority of patients who experience systemic reactions after Hymenoptera stings have IgE-mediated sensitivity to antigenic substances in the venom. Some venom allergens are homologous among members of the Hymenoptera order; others are family specific. There is substantial cross-reactivity among vespid venoms, but these venom allergens are distinct from honeybee venom allergens.

Localized skin responses to biting insects are caused primarily by vasoactive or irritant materials derived from insect saliva, and rarely occur from IgE-associated responses. Systemic IgE-mediated allergic reactions to salivary proteins of biting insects such as mosquitoes are reported but uncommon.

A variety of proteins derived from insects can become airborne and induce IgE-mediated respiratory responses, causing inhalant allergies. The primary allergen from the caddis fly is a hemocyanin-like protein, and that from the midge fly is derived from hemoglobin. Allergens from the cockroach are the best studied and are derived from cockroach saliva, secretions, fecal material, and debris from skin casts.

**CLINICAL MANIFESTATIONS**

Clinical reactions to stinging venomous insects are categorized as local, regional, or systemic. Local reactions involve limited swelling and pain, and generally last <24 hr. Large local reactions develop over hours and days, involve swelling of extensive areas (>10 cm) that are contiguous with the sting site, and may last for days. Generalized cutaneous reactions typically progress within minutes and include cutaneous symptoms of urticaria, angioedema, and pruritus beyond the site of the sting. Systemic reactions are identical to anaphylaxis from other triggers and may include symptoms of generalized urticaria, laryngeal edema, bronchospasm, and hypotension. Stings from a large number of insects at once may result in toxic reactions of fever, malaise, emesis, and nausea owing to the chemical properties of the venom in large doses. Serum sickness, nephrotic syndrome, vasculitis, neuritis, or encephalopathy may occur as delayed/late reactions to stinging insects.

Insect bites are usually urticarial but may be papular or vesicular. Papular urticaria affecting the lower extremities in children is usually caused by multiple bites. Occasionally, individuals have large local reactions. IgE antibody–associated immediate- and late-phase allergic responses to mosquito bites sometimes mimic cellulitis.

Inhalant allergy caused by insects results in clinical disease similar to that induced by other inhalant allergens such as pollens. Depending on individual sensitivity and exposure, reactions may result in seasonal or perennial rhinitis, conjunctivitis, and/or asthma.

**DIAGNOSIS**

The diagnosis of allergy from stinging and biting insects is generally evident from the history of exposure, typical symptoms, and physical findings. The diagnosis of Hymenoptera allergy rests in part on the identification of venom-specific IgE by prick skin testing or in vitro testing. The primary reasons to pursue testing are to confirm reactivity when venom immunotherapy (VIT) is being considered or when it is clinically necessary to confirm venom hypersensitivity as a cause of a reaction. Venoms of 5 Hymenoptera (honeybee, yellow jacket, yellow
hymenoptera (hornet, white-faced hornet, and wasp), as well as the jack jumper ant in Australia and whole-body extract of fire ant, are available for skin testing. Although skin tests are considered to be the most sensitive modality for detection of venom-specific IgE, additional evaluation with an in vitro serum assay for venom-specific IgE is recommended if skin test results are negative in the presence of a convincing history of a severe systemic reaction. With in vitro tests, there is a 20% incidence of both false-positive and false-negative results, so it is not appropriate to exclude venom hypersensitivity based on this test alone. If initial skin prick and in vitro test results are negative in the context of a convincing history of a severe reaction, repeat testing is recommended before concluding that allergy is unlikely. Skin tests are usually accurate within 1 wk of a sting reaction, but occasionally a refractory period is observed that warrants retesting after 4-6 wk if the initial results are negative. If repeat skin prick and in vitro results are still negative despite a convincing history, occult mast cell disorders should be considered and a baseline serum tryptase should be measured. As many as 40% of skin test–positive subjects may not experience anaphylaxis on sting challenge, so testing without an appropriate clinical history is potentially misleading.

The diagnosis of inhalant insect allergy may be evident from a history of typical symptoms. A chronic respiratory symptom during long-term exposure, as may occur with cockroach allergy, is less amenable to identification by history alone. Skin prick or in vitro immunoassay tests for specific IgE to the insect are used to confirm inhalant insect allergy. Allergy tests may be particularly warranted for potential cockroach allergy in patients with persistent asthma and known cockroach exposure.

**TREATMENT**

For local cutaneous reactions caused by insect stings and bites, treatment with cold compresses, topical medications to relieve itching, and, occasionally, the use of a systemic antihistamine and oral analgesic are appropriate. Stingers should be removed promptly by scraping, with caution not to squeeze the venom sac because doing so could inject more venom. Sting sites rarely become infected, possibly owing to the antibacterial actions of venom constituents. Vesicles left by fire ant stings that are scratched open should be cleansed to prevent secondary infection.

Anaphylactic reactions after a Hymenoptera sting are treated exactly like anaphylaxis from any cause; epinephrine is the drug of choice. Adjunctive treatment includes antihistamines, corticosteroids, intravenous fluids, oxygen, and transport to the emergency room. (see Chapter 149). Referral to an allergist-immunologist should be considered for patients who have experienced a generalized cutaneous or systemic reaction to an insect sting, need education about avoidance and emergency treatment, may be candidates for VIT, or have a condition that may complicate management of anaphylaxis (e.g., use of β-blockers).

**Venom Immunotherapy**

Hymenoptera VIT is highly effective (95-97%) in decreasing the risk for severe anaphylaxis. The selection of patients for VIT depends on several factors (Table 146-1). Individuals with local reactions regardless of age are not at increased risk for severe systemic reactions on a subsequent sting and are not candidates for VIT. The risk of a systemic reaction for those who experienced a large local reaction is no more than 5-10%; testing or VIT is usually not recommended, and prescription of self-injectable epinephrine is considered optional but usually not necessary. There is growing evidence that VIT can reduce the size and duration of large, local reactions, and therefore VIT may be considered for those with frequent or unavoidable large, local reactions. Those who experience severe systemic reactions, such as airway involvement or hypotension, and have specific IgE to venom allergens should receive immunotherapy. Immunotherapy against winged Hymenoptera is not usually indicated for children ≤16 yr of age in whom stings have caused only generalized urticaria or angioedema, because their risk for a systemic reaction after a subsequent sting is approximately 10%. If a systemic reaction does occur, it is likely to be isolated skin reactions, with <5% risk of a more severe reaction and <1% risk of life-threatening anaphylaxis. The risk could be reduced to 1% after treatment with VIT, so it is an option to consider if multiple future stings are anticipated. Immunotherapy against Hymenoptera is indicated in those ≥17 yr of age who have specific IgE to venom allergens and a history of generalized urticaria or a systemic reaction, because their risk for future systemic reactions is 30-60%. VIT is usually not indicated if there is no evidence of IgE to venom.

The incidence of adverse effects in the course of treatment is not trivial in adults, as 50% experience large local reactions and about 10% experience systemic reactions. The incidence of both local and systemic reactions is much lower in children. Patients treated with honeybee venom are at higher risk for systemic reactions to VIT than those receiving treatment with vespid venom. Individuals with mast cell disorders are at increased risk for severe anaphylaxis and more frequent systemic reactions with VIT.

It is uncertain how long immunotherapy with Hymenoptera venom should continue. In general, a 3-5 year treatment duration is recommended because >80% of adults who have received 5 yr of therapy tolerate challenge stings without systemic reactions for 5-10 yr after completion of treatment. Long-term responses to treatment are even better for children. Follow-up over a mean of 18 yr of children with moderate to severe insect sting reactions who received VIT for a mean treatment period of 3-5 yr and were stung again showed a reaction rate of only 5%; untreated children experienced a reaction rate of 32%. Whereas duration of therapy with VIT may be individualized, it is clear that a significant number of untreated children retain their allergy. Lifelong treatment may be considered for those who have had severe life-threatening anaphylaxis with insect stings, those with honeybee allergy, and those with occupational exposures to Hymenoptera. Life-long VIT should also be considered for those with mast cell disorders as these individuals have a higher rate of failure of VIT and relapse when VIT is discontinued.

Less is known about the natural history of fire ant hypersensitivity and efficacy of immunotherapy for this allergy. The criteria for starting immunotherapy are similar to those for hypersensitivities to other Hymenoptera, but there is stronger consideration to treat children ≤16 yr of age with VIT if they have experienced only generalized

*Risks generally decrease after 10 yr.*
urticaria. Only whole-body fire ant extract is commercially available for diagnostic skin testing and immunotherapy.

**Inhalant Allergy**
The symptoms of inhalant allergy caused by insects are managed as for other causes of seasonal or perennial rhinitis (see Chapter 143), conjunctivitis (see Chapter 147), and asthma (see Chapter 144).

**PREVENTION**
Avoidance of stings and bites is essential. To reduce the risk of stings, sensitized individuals should avoid attractants such as perfumes and bright-colored clothing outdoors, wear gloves when gardening, and wear long pants and shoes with socks when walking in the grass or through fields. Typical insect repellents do not guard against Hymenoptera. Nests of these insects should be removed if they are close to the home.

*Individuals who have had generalized cutaneous or systemic reactions to Hymenoptera stings should have immediate access to self-injectable epinephrine.* Adults responsible for allergic children, and older patients who can self-treat, must be carefully taught the indications for and technique of administration of this medication. Particular attention is necessary for children in out-of-home daycare centers, at school, or attending camps, to ensure that an emergency action plan is in place. The individual at risk for anaphylaxis from an insect sting should also wear an identification bracelet indicating the allergy.

Avoidance of the insect is the preferred management of inhalant allergy. This can prove difficult, particularly, for instance, for those living in multiple-dwelling apartments, where eradication of cockroaches is problematic. Immunotherapy for dust mites is effective and should be considered in conjunction with avoidance measures. In contrast, there is limited data regarding the efficacy of cockroach immunotherapy.

*Bibliography is available at Expert Consult.*
Bibliography
The eye is a common target of allergic disorders because of its marked vascularity and direct contact with allergens in the environment. The conjunctiva is the most immunologically active tissue of the external eye. Ocular allergies can occur as isolated target organ disease or more commonly in conjunction with nasal allergies. Ocular symptoms can significantly affect quality of life.

CLINICAL MANIFESTATIONS
There are a few distinct entities that constitute allergic eye disease, all of which have bilateral involvement. Sensitization is necessary for all of these except for giant papillary conjunctivitis. Vernal keratoconjunctivitis and atopic keratoconjunctivitis are potentially sight-threatening.

Allergic Conjunctivitis
Allergic conjunctivitis is the most common hypersensitivity response of the eye, affecting approximately 25% of the general population and 30% of children with atopy. It is caused by direct exposure of the mucosal surfaces of the eye to environmental allergens. Patients complain of variable ocular itching, rather than pain, with increased tearing. Clinical signs include bilateral injected conjunctivae with vascular congestion that may progress to chemosis, or conjunctival swelling, and a watery discharge (Fig. 147-1). Allergic conjunctivitis occurs in a seasonal or, less commonly, perennial form. Seasonal allergic conjunctivitis is typically associated with allergic rhinitis (see Chapter 143) and is most commonly triggered by pollens. Major pollen groups in the temperate zones include trees (late winter to early spring), grasses (late spring to early summer), and weeds (late summer to early fall), but seasons can vary significantly in different parts of the country. Mold spores can also cause seasonal allergy symptoms, principally in the summer and fall. Seasonal allergy symptoms may be aggravated by coincident exposure to perennial allergens. Perennial allergic conjunctivitis is triggered by allergens such as animal danders or dust mites that are present throughout the year. Symptoms are usually less severe than with seasonal allergic conjunctivitis. Because pollens and soil molds may be present intermittently by season, and exposure to allergens such as furred animals may be perennial, classification as intermittent (symptoms present <4 days/wk or for <4 wk) and persistent (symptoms present >4 days/wk and for >4 wk) has been proposed.

Vernal Keratoconjunctivitis
Vernal keratoconjunctivitis is a severe bilateral chronic inflammatory process of the upper tarsal conjunctival surface that occurs in a limbal or palpebral form. It may threaten eyesight if there is corneal involvement. Although vernal keratoconjunctivitis is not immunoglobulin E mediated, it occurs most frequently in children with seasonal allergies, asthma, or atopic dermatitis. Vernal keratoconjunctivitis affects boys twice as often as girls and is more common in persons of Asian and African descent. It affects primarily children in temperate areas, with exacerbations in the spring and summer. Symptoms include severe ocular itching exacerbated by exposure to irritants, light, or perspiration. In addition, patients may complain of severe photophobia, foreign-body sensation, and lacrimation. Giant papillae occur predominantly on the upper tarsal plate and are typically described as cobblestoning (Fig. 147-2). Other signs include a stringy or thick, ropey discharge, cobblestone papillae, transient yellow-white points in the limbus (Trantas dots) and conjunctiva (Horner points), corneal “shield” ulcers, and Dennie lines (Dennie-Morgan folds), which are prominent symmetric skinfolds that extend in an arc from the inner canthus beneath and parallel to the lower lid margin. Children with vernal keratoconjunctivitis have measurably longer eyelashes, which may represent a reaction to ocular inflammation.

Atopic Keratoconjunctivitis
Atopic keratoconjunctivitis is a chronic inflammatory ocular disorder most commonly involving the lower tarsal conjunctiva. It may threaten eyesight if there is corneal involvement. Almost all patients have atopic dermatitis, and a significant number have asthma. Atopic
keratoconjunctivitis rarely presents before late adolescence. Symptoms include severe bilateral ocular itching, burning, photophobia, and tearing with a mucoid discharge that are much more severe than in allergic conjunctivitis and persist throughout the year. The bulbar conjunctiva is injected and chemotic; cataracts may occur. Trantas dots or giant papillae may also be present. Eyelid eczema can extend to the periorbital skin and cheeks with erythema and thick, dry scaling. Secondary staphylococcal blepharitis is common because of eyelid induration and maceration.

**Giant Papillary Conjunctivitis**

Giant papillary conjunctivitis has been linked to chronic exposure to foreign bodies, such as contact lenses, both hard and soft, ocular prostheses, and sutures. Symptoms and signs include mild bilateral ocular itching, tearing, a foreign-body sensation, and excessive ocular discomfort with mild mucoid discharge with white or clear exudate on awakening, which may become thick and stringy. Trantas dots, limbal infiltration, bulbar conjunctival hyperemia, and edema may develop.

**Contact Allergy**

Contact allergy typically involves the eyelids but can also involve the conjunctivae. It is being recognized more frequently in association with increased exposure to topical medications, contact lens solutions, and preservatives.

**DIAGNOSIS**

Nonallergic conjunctivitis can be viral, bacterial, or chlamydial in origin. It is typically unilateral but can be bilateral with symptoms initially developing in 1 eye (see Chapter 626). Symptoms include stinging or burning rather than itching and often a foreign-body sensation. Ocular discharge can be watery, mucoid, or purulent. Masqueraders of ocular allergy also include nasolacrimal duct obstruction, foreign body, blepharoconjunctivitis, dry eye, uveitis, and trauma.

**TREATMENT**

Primary treatment of ocular allergies includes avoidance of allergens, cold compresses, and lubrication. Secondary treatment regimens include the use of oral or topical antihistamines and, if necessary, topical decongestants, mast cell stabilizers, and antiinflammatory agents (Table 147-1). Drugs with dual antihistamine and mast cell blocking activities provide the most advantageous approach in treating allergic conjunctivitis, with both fast-acting symptomatic relief and long-term control of symptoms.

Figure 147-2 Vernal keratoconjunctivitis. Cobblestone papillae and ropey discharge are seen on the underside (tarsal conjunctiva) of the upper eyelid. (From Adkinson NF Jr, Bochner BS, Busse WW, et al, editors: Middleton’s allergy principles and practice, ed 7, vol 2, Philadelphia, Mosby/Elsevier, 2009, p. 1124.)
Ketotifen fumarate 0.025%
Zaditor
Antihistamine/mast cell stabilizer
Children ≥3 yr: 1 gtt bid q8-12h
Not for treatment of contact lens–related irritation; the preservative may be absorbed by soft contact lenses. Wait at least 10 min after administration before inserting soft contact lenses.

Olopatadine hydrochloride 0.1%, 0.2%
Patanol
Pataday
Antihistamine/mast cell stabilizer
Children ≥3 yr: 1 gtt bid (8 hr apart) 1 gtt q day
Not for treatment of contact lens–related irritation; the preservative may be absorbed by soft contact lenses. Wait at least 10 min after administration before inserting soft contact lenses.

Alcaftadine, 0.25%
Lastacaft
Antihistamine/mast cell stabilizer
Children >2 yr: 1 gtt bid q8-12 hr
Contact lenses should be removed prior to application, may be inserted after 10 minutes. Not for the treatment of contact lens irritation.

Bepotastine besilate 1.5%
Bepreve
Antihistamine/mast cell stabilizer
Children >2 yr: 1 gtt bid q8-12 hr
Contact lenses should be removed prior to application, may be inserted after 10 minutes. Not for the treatment of contact lens irritation.

Ketorolac tromethamine 0.5%
Acular
NSAID
Children ≥3 yr: 1 gtt qid
Avoid with aspirin or NSAID sensitivity. Use ocular product with caution in patients with complicated ocular surgeries, corneal denervation or epithelial defects, ocular surface diseases (e.g., dry eye syndrome), repeated ocular surgeries within a short period of time, diabetes mellitus, or rheumatoid arthritis; these patients may be at risk for corneal adverse events that may be sight-threatening. Do not use while wearing contact lenses.

Fluorometholone 0.1%, 0.25% suspension (0.1%, 0.25%)
and ointment (0.1%)
FML, FML Forte, Flarex
Fluorinated corticosteroid
Children ≥2 yr: 1 gtt into conjunctival sac of affected eye(s) bid-qid. During initial 24–48 hr, dosage may be increased to 1 gtt q 4 hr. Ointment (approximately 1.3 cm in length) into the conjunctival sac of affected eye(s) 1–3 times daily. May be applied q 4 hr during initial 24–48 hr of therapy
If improvement does not occur after 2 days, patient should be reevaluated. Patient should remove soft contact lenses prior to administering (contains benzalkonium chloride) and delay reinsertion of lenses for ≥15 minutes after administration. Close monitoring for development of glaucoma and cataracts.

NSAID, nonsteroidal antiinflammatory drug.
Bibliography

Urticaria and angioedema affect 20% of individuals at some point in their lives. Episodes of hives that last for <6 wk are considered acute, whereas those that occur on most days of the week for >6 wks are designated chronic. The distinction is important, because the causes and mechanisms of urticaria formation and the therapeutic approaches are different in each instance.

**ETIOLOGY AND PATHOGENESIS**

Acute urticaria and angioedema are often caused by an allergic immunoglobulin (Ig) E–mediated reaction (Table 148-1). This form of urticaria is a self-limited process that occurs when an allergen activates mast cells in the skin. Common causes of acute generalized urticaria include foods, drugs (particularly antibiotics), and stinging insect venoms. If an allergen (latex, animal dander) penetrates the skin locally, hives often can develop at the site of exposure. Acute urticaria can also result from non–IgE-mediated stimulation of mast cells,
caused by radiocontrast agents, viral agents (including hepatitis B and Epstein-Barr virus), opiates, and nonsteroidal antiinflammatory agents. The diagnosis of chronic urticaria is established when lesions occur on most days of the week for >6 wk and are not physical urticaria or recurrent acute urticaria with repeated exposures to a specific agent (Table 148-2). In about half the cases, chronic urticaria is accompanied by angioedema. Rarely, angioedema occurs without urticaria. Angioedema without urticaria is often a result of allergy, but recurrent angioedema raises a question about other diagnoses.

A typical hive is an erythematous, pruritic raised wheal that blanches with pressure, is transient, and resolves without residual lesions, unless the area was intensely scratched. In contrast, urticaria associated with serum sickness reactions, systemic lupus erythematosus or other vasculitides, in which a skin biopsy reveals a small-vessel vasculitis, often have distinguishing clinical features. Lesions that burn more than itch, last >24 hr, do not blanch, blister, heal with scarring, or are associated with bleeding into the skin (purpura) suggest urticarial vasculitis. Atypical aspects of the gross appearance of the hives or associated symptoms should heighten concern that the urticaria or angioedema may be the manifestation of a systemic disease process.

**Physical Urticaria**
Physically induced urticaria and angioedema share the common property of being induced by an environmental stimulus, such as a change in temperature or direct stimulation of the skin with pressure, stroking, vibration, or light (Table 148-3).

**Cold-Dependent Disorders**
Cold urticaria is characterized by the development of localized pruri-tus, erythema, and urticaria/angioedema after exposure to a cold stimulus. Total-body exposure as seen with swimming in cold water can cause massive release of vasoactive mediators, resulting in hypotension, loss of consciousness and even death if not promptly treated. The diagnosis is confirmed by challenge testing for an isomorphic cold reaction by holding an ice cube in place on the patient’s skin for 4 min. In patients with cold urticaria, an urticarial lesion develops about 10 minutes after removal of the ice cube and upon rewarming of the chilled skin. Cold urticaria can be associated with the presence of cryoproteins, such as cold agglutinins, cryoglobulins, cryofibrinogen, and the Donath-Landsteiner antibody seen in secondary syphilis (paroxysmal cold hemoglobinuria). In patients with cryoglobulins, the isolated proteins appear to transfer cold sensitivity and activate the complement cascade upon in vitro incubation with normal plasma. The term idiopathic cold urticaria generally applies to patients without abnormal circulating plasma proteins such as cryoglobulins. Cold urticaria has also been reported after viral infections. Cold urticaria must be distinguished from the familial cold autoinflammatory syndrome (see “Diagnosis,” later).

**Cholinergic Urticaria**
Cholinergic urticaria is characterized by the onset of small punctate pruritic wheals surrounded by a prominent erythematous flare associated with exercise, hot showers, and sweating. Once the patient cools down, the rash usually subsides in 30-60 min. Occasionally, symptoms of more generalized cholinergic stimulation, such as lacrimation, wheezing, salivation, and syncope, are observed. These symptoms are mediated by cholinergic nerve fibers that innervate the musculature via parasympathetic neurons and innervate the sweat glands by cholinergic fibers that travel with the sympathetic nerves. Elevated plasma histamine values parallel the onset of urticaria triggered by changes in body temperature.

**Dermatographism**
The ability to write on skin, termed dermatographism (also called dermographism or urticaria factitia), may occur as an isolated

**DIAGNOSIS** | **DIAGNOSTIC TESTING**
--- | ---
Food and drug reactions | Elimination of offending agent, skin testing, and challenge with suspected foods
Autoimmune urticaria | Autologous serum skin test; antihistamine antibodies; antibodies against the high-affinity IgE receptor
Thyroiditis | Thyroid-stimulating hormone; antihistamine antibodies
Infections | Appropriate cultures or serology
Collagen vascular diseases and cutaneous vasculitis | Skin biopsy, CH₅₀, C₁q, C₄, C₃, factor B, immunofluorescence of tissues, antinuclear antibodies, cryoglobulins
Malignancy with angioedema | CH₅₀, C₁q, C₄, C₁-INH determinations
Cold urticaria | Ice cube test
Solar urticaria | Exposure to defined wavelengths of light, red blood cell protoporphyrin, fecal protoporphyrin, and coproporphyrin
Dermatographism | Stroking with narrow object (e.g., tongue blade, fingernail)
Pressure urticaria | Application of pressure for defined time and intensity
Vibratory urticaria | Vibration for 4 min
Aquagenic urticaria | Challenge with tap water at various temperatures
Urticaria pigmentosa | Skin biopsy, test for dermographism
Hereditary angioedema | C₄, C₂, CH₅₀, C₁-INH testing by protein and function
Familial cold urticaria | Challenge by cold exposure, measurement of temperature, white blood cell count, erythrocyte sedimentation rate, and skin biopsy
C₃b inactivator deficiency | C₃, factor B, C₃b inactivator determinations
Chronic idiopathic urticaria | Skin biopsy, immunofluorescence (negative result), autologous skin test

**Solar Urticaria**
Solar urticaria is a rare disorder in which urticaria develops within minutes of direct sun exposure. Typically, pruritus occurs first, in approximately 30 sec, followed by edema confined to the light-exposed area and surrounded by a prominent erythematous zone. The lesions usually disappear within 1-3 hr after cessation of sun exposure. When large areas of the body are exposed, systemic symptoms may occur, including hypotension and wheezing. Solar urticaria has been classified into 6 types, depending on (1) the wavelength of light that induces skin lesions and (2) the ability or inability to transfer the disorder passively with serum IgE. The rare inborn error of metabolism, *erythropoietic protoporphyria*, can be confused with solar urticaria because of the development of itching and burning of exposed skin immediately after sun exposure. In erythropoietic protoporphyria, fluorescence of ultraviolet-irradiated red blood cells can be demonstrated and protoporphyins are found in the urine.

**Aquagenic Urticaria**
Patients with aquagenic urticaria demonstrate small wheals after contact with water, regardless of its temperature, and are thereby distinguishable from patients with cold urticaria or cholinergic urticaria. Direct application of a compress of water to the skin is used to test for the presence of aquagenic urticaria. In some of these patients, chlorine or other trace contaminants are responsible for the reaction.

**CHRONIC IDIOPATHIC URTICARIA AND ANGIOEDEMA**
A common disorder of unknown origin, chronic idiopathic urticaria and angioedema is often associated with normal routine laboratory values and no evidence of systemic disease. Chronic urticaria does not appear to result from an allergic reaction. It differs from allergen-induced skin reactions and from physically induced urticaria in that histologic studies reveal a cellular infiltrate predominantly around small venules. Skin examination reveals infiltrative hives with palpably elevated borders, sometimes varying greatly in size and/or shape but generally being rounded.

Biopsy of the typical lesion reveals non-necrotizing, perivascular, mononuclear cellular infiltration. Many types of histopathologic processes can occur in the skin and manifest as urticaria. Patients with *hypocomplementemia* and *cutaneous vasculitis* can have urticaria and/or angioedema. Biopsy of these lesions in patients with urticaria, arthralgias, myalgias, and an elevated erythrocyte sedimentation rate (ESR) as manifestations of necrotizing venulitis can reveal fibrinoid necrosis with a predominantly neutrophilic infiltrate. Yet the urticarial lesions may be clinically indistinguishable from those seen in the more typical, nonvasculitic cases.

There is an increased association of chronic urticaria with the presence of antithyroid antibodies. Affected patients generally have antibodies to thyroglobulin or a microsomal-derived antigen (peroxidase) even if they are euthyroid. The incidence of elevated thyroid antibodies in patients with chronic urticaria is ≈12%, compared with 3-6% in the general population. Although some patients show clinical reduction of the urticaria with thyroid replacement therapy, others do not. The role of thyroid autoantibodies in chronic urticaria is uncertain. It has been proposed that their presence may reflect a tendency of the patient to develop autoantibodies, but that they may not play a direct role in chronic urticaria. Of patients with chronic urticaria, 35-40% have a positive *autologous serum skin test* result: If serum from these patients is intradermally injected into their skin, a significant wheal and flare reaction develops. Such patients frequently have a complement-activating IgE antibody directed against the α subunit of the IgE receptor that can crosslink the IgE receptor (α subunit) and degranulate mast cells and basophils. An additional 5-10% of patients
with chronic urticaria have anti-IgE antibodies rather than an anti-IgE receptor antibody. These patients, classified as having autoimmune urticaria, tend to have a more severe clinical course than patients without evidence of autoantibodies, but the difference is not dramatic.

**DIAGNOSIS**

The diagnosis of both acute and chronic urticaria is primarily clinical and requires that the physician be aware of the various forms of urticaria.

**Urticaria** is transient, pruritic, erythematous, raised wheals, with flat tops and edema that may become tense and painful. The lesions may coalesce and form polycyclic, serpiginous, or annular lesions (Figs. 148-1 and 148-2). Individual lesions usually last 20 min to 3 hr, and rarely more than 24 hr. The lesions often disappear only to reappear at another site. **Angioedema** involves the deeper subcutaneous tissues in locations such as the eyelids, lips, tongue, genitals, dorsum of the hands or feet, or wall of the gastrointestinal (GI) tract.

Drugs and foods are the most common causes of acute urticaria. Allergy skin testing for foods can be helpful in sorting out causes of acute urticaria, especially when supported by historical evidence. The role of an offending food can then be proven by elimination and careful challenge in a controlled setting. In the absence of information implicating an ingestant cause, skin testing for foods and implementation of elimination diets are generally not useful for either acute or chronic urticaria. Patients with delayed urticaria 3-6 hr after a meal consisting of mammalian meat should be evaluated for IgE to galactose-alpha-1,3-galactose ("alpha-gal"), a carbohydrate moiety. Alpha-gal has been identified as a trigger in this circumstance, with sensitization apparently linked to tick bites in specific geographic regions, such as the mid-Atlantic area of the United States. Skin testing for aeroallergens is not indicated unless there is a concern about contact urticaria (animal dander or grass pollen). Dermatographism is frequent in patients with urticaria and can complicate allergy skin testing by causing false-positive reactions, but this distinction is usually discernable.

An exogenous cause of chronic urticaria is rarely identified, reflecting the wide variety of allergens with which we come in contact. Autoimmune diseases are rare causes of chronic urticarial or angioedema. An autologous serum skin test may be useful in establishing the diagnosis of autoimmune urticaria. In vitro testing for serum-derived activity that activates basophils involves detection of the expression of the surface marker CD63 or CD203c by donor basophils after incubation with patient serum. The clinical applicability and significance of these tests remains debated. The **differential diagnosis** of chronic urticaria includes cutaneous or systemic mastocytosis, complement-mediated mast cell degranulation as may occur with the presence of circulating immune complexes, malignancies, mixed connective tissue diseases, and cutaneous blistering disorders (e.g., bullous pemphigoid; see Table 148-2). In general, laboratory testing should be limited to a complete blood cell count with differential, ESR determination, urinalysis, thyroid autoantibody testing, and liver function tests. Further studies are warranted if the patient has fever, arthralgias, or elevated ESR (see Table 148-3). Testing for antibodies directed at the high affinity IgE receptor may be warranted in patients with intractable urticaria. Hereditary angioedema, a potentially life-threatening form of angioedema usually associated with deficient C1 inhibitor activity, is the most important familial form of angioedema (see Chapter 134.3), but is not associated with typical urticaria. In patients with eosinophilia, stools should be obtained for ova and parasite testing, because infection with helminthic parasites has been associated with urticaria. A syndrome of episodic angioedema/urticaria and fever with associated eosinophilia has been described in both adults and children. In contrast to other hypereosinophilic syndromes, this entity has a benign course.

Skin biopsy for diagnosis of possible **urticular vasculitis** is recommended for urticarial lesions that persist at the same location for >24 hr, those with pigmented or purpuric components, and those that burn more than itch. Collagen vascular diseases such as systemic lupus may manifest urticarial vasculitis as a presenting feature. The skin biopsy in urticarial vasculitits typically shows endothelial cell swelling of postcapillary venules with necrosis of the vessel wall, perivascular neutrophil infiltrate, diapedesis of red blood cells, and fibrin deposition associated with deposition of immune complexes.

**Mastocytosis** is characterized by mast cell hyperplasia in the bone marrow, liver, spleen, lymph nodes, and skin. Clinical effects of mast cell activation are common, including pruritus, flushing, urtication, abdominal pain, nausea, and vomiting. The diagnosis is confirmed by a bone marrow biopsy showing increased numbers of spindle-shaped mast cells that express CD2 and CD25. **Urticaria pigmentosa** is the most common skin manifestation of mastocytosis and may occur as an isolated skin finding. It appears as small, yellow-to reddish brown macules or raised papules that urticate on scratching (**Darier sign**). This sign can be masked by antihistamines. The diagnosis is confirmed by a skin biopsy that shows increased numbers of dermal mast cells.

Physical urticaria should be considered in any patient with chronic urticaria and a suggestive history (see Table 148-3). Papular urticaria commonly occurs in small children, generally on the extremities. It manifests as grouped or linear, highly pruritic wheals or papules mainly on exposed skin at the sites of insect bites.

Exercise-induced anaphylaxis manifests as varying combinations of pruritus, urticaria, angioedema, wheezing, laryngeal obstruction, or hypotension after exercise (see Chapter 149). Cholinergic urticaria is differentiated by positive results of heat challenge tests and the rare occurrence of anaphylactic shock. The combination of ingestion of various food allergens (shrimp, celery, or wheat) and postprandial exercise has been associated with urticaria/angioedema and
anaphylaxis. In patients with this combination disorder, food or exercise alone does not produce the reaction.

Muckle–Wells syndrome and familial cold autoinflammatory syndrome are rare, dominantly inherited conditions associated with recurrent urticaria-like lesions. Muckle–Wells syndrome is characterized by arthritis and joint pain that usually appears in adolescence. It is associated with progressive nerve deafness, recurrent fever, elevated ESR, hypergamma globulinemia, renal amyloidosis, and a poor prognosis. Familial cold autoinflammatory syndrome is characterized by a cold-induced rash that has urticarial features but is rarely pruritic. Cold exposure leads to additional symptoms such as conjunctivitis, sweating, headache, and nausea. Patient longevity is usually normal.

**TREATMENT**

Acute urticaria is a self-limited illness requiring little treatment other than antihistamines and avoidance of any identified trigger. Hydroxyzine and diphenhydramine are sedating but are effective and commonly used for treatment of urticaria. Loratadine, fexofenadine, and cetirizine are also effective and are preferable because of reduced frequency of drowsiness and longer duration of action (Table 148-4). Epinephrine 1:1,000, 0.01 mL/kg (maximum: 0.3 mL) intramuscularly usually provides rapid relief of acute, severe urticaria/angioedema but is seldom required. A short course of oral corticosteroids should be given only for very severe episodes of urticaria and angioedema that are unresponsive to antihistamines.

The best treatment of physical urticaria is avoidance of the stimulus. Antihistamines are also helpful. Cyproheptadine in divided doses is the drug of choice for cold-induced urticaria. Treatment of dermatographism consists of local skin care and antihistamines; for severe symptoms, high doses may be needed. The initial objective of therapy is to decrease pruritus so that the stimulation for scratching is diminished. A combination of antihistamines, sunscreens, and avoidance of sunlight is helpful for most patients.

Chronic urticaria only rarely responds favorably to dietary manipulation. Removal of recognized urticarial aggravators such as salicylates and β-blockers should be considered. The mainstay of therapy is the use of nonsedating or low-sedating H₁ antihistamines. In those patients not showing response to standard doses, pushing the H₁ blockade with higher than the usual recommended doses of these agents is a common next approach. The 3-drug combination of H₁ and H₂ antihistamine combined with a leukotriene receptor antagonist (montelukast) is helpful for many patients. If hives persist after maximal H₁- and/or H₂-receptor blockade has been achieved, a brief course of oral corticosteroids may be considered, but long-term steroid use is best avoided. Treatment with cyclosporine 4-6 mg/kg/day has been effective in some adults with chronic urticaria but its use is limited by hypertension and/or nephrotoxicity. Immunomodulatory agents such as omalizumab (anti-IgE antibody) that have been used with success in cases of chronic urticarial that are refractory to other therapies, but are not approved for the treatment of this condition by the FDA. These include omalizumab (anti-IgE), cyclosporine, hydroxychloroquine, sulfasalazine, colchicine, dapsone, mycophenolate, intravenous immunoglobulin, and plasmapheresis.

**HEREDITARY ANGIOEDEMA**

Hereditary angioedema (HAE) (types 1 and 2) is an inherited autosomal dominant disease caused by low functional levels of the plasma protein C1 inhibitor (C1-INH) (see Chapter 134). Patients typically report episodic attacks of angioedema or deep localized swelling, most commonly on a hand or foot, that begin during childhood and become much more severe during adolescence. Cutaneous nonpitting, non-pruritic edema not associated with urticaria is the most common symptom. The swelling usually becomes more severe over about 1.5 days and then resolves over about the same period. In some patients attacks are preceded by the development of a rash, that is erythematosum marginatum, that is erythematous, not raised, and not pruritic. The second major symptom complex noted by patients is attacks of severe abdominal pain caused by edema of the mucosa of any portion of the GI tract. The intensity of the pain can approximate that of an acute abdomen, often resulting in unnecessary surgery. Either constipation or diarrhea during these attacks can be noted. The GI edema generally follows the same time course to resolution as the cutaneous attacks, and often does not occur at the same time as the peripheral edema. Patients usually have a prodrome, a tightness or tingling in the area that will swell, lasting most frequently for several hours, followed by the development of angioedema.

Laryngeal edema, the most feared complication of HAE, can cause complete respiratory obstruction. Although life-threatening attacks are infrequent, more than half of patients with HAE experience laryngeal involvement at some time during their lives. Dental work with the injection of procaine HCL (Novocain) into the gums is a common precipitant, but laryngeal edema can be spontaneous. The clinical condition may deteriorate rapidly, progressing through mild discomfort to complete airway obstruction over a period of hours. Soft-tissue edema can be readily seen when the disease involves the throat and uvula. If this edema progresses to difficulty swallowing secretions or a change in the tone of the voice, the patient may require emergency intubation or even tracheostomy to ensure an adequate airway. Other presentations are less common. These patients typically do not respond well to treatment with epinephrine, antihistamines, or glucocorticoids.

In most cases the cause of the attack is unknown, but in some patients trauma or emotional stress clearly precipitates attacks. Drugs like angiotensin-converting enzyme inhibitors that inhibit the degradation of bradykinin make the disease strikingly worse, and estrogens also make attacks more severe. In some females menstruation also regularly induces attacks. The frequency of attacks varies greatly among
affected individuals and at different times in the same individual. Some individuals experience weekly episodes, whereas others may go years between attacks. Episodes can start at any age.

C1-INH is a member of the serpin family of proteases, similar to α-antitrypsin, antithrombin III, and angiotensinogen. These proteins stoichiometrically inactivate their target proteases by forming stable, 1:1 complexes with the protein to be inhibited. Synthesized primarily by hepatocytes, C1-INH is also synthesized by monocytes. The regulation of the protein production is not completely understood, but it is believed that androgens may stimulate C1-INH synthesis, because patients with the disorder respond clinically to androgen therapy with raised serum levels of C1-INH. C1-INH deficiency is an autosomal dominant disease, with as many as 25% of patients giving no family history. Because all C1-INH–deficient patients are heterozygous for this gene defect, it is believed that half the normal level of C1-INH is not sufficient to prevent attacks.

Although named for its action on the first component of complement (C1 esterase), C1-INH also inhibits components of the fibrinolytic, clotting, and kinin pathways. Specifically, C1-INH inactivates plasmin–activated Hageman factor (factor XII), activated factor XI, plasma thromboplastin antecedent, and kallikrein. Within the complement system, C1-INH blocks the activation of C1 and the rest of the classic complement pathway by binding to C1r and C1s. Without adequate C1-INH, unchecked activation of C1 causes cleavage of C4 and C2, the following proteins in the complement cascade. Levels of C3 are normal. The major factor responsible for the edema formation is now known to be bradykinin, an important nonapeptide mediator that can induce leakage of postcapillary venules. Bradykinin is derived from cleavage of the circulating protein high molecular weight kininogen by the plasma enzyme kallikrein.

Two genetic types of C1-INH deficiency are described that result in essentially the same phenotypic expression. The C1-INH gene is located on chromosome 11 in the p11-q13 region. The inheritance is autosomal dominant with incomplete penetrance. Persons inheriting the abnormal gene can have a clinical spectrum ranging from asymptomatic to severely affected. Type 1 HAE is the most common form, accounting for approximately 85% of cases. Synthesis of C1-INH is blocked at the site of the faulty allele or the protein is not secreted normally because of faulty protein processing, but secretion occurs at the normal allele. The result is secretion of the normal protein, yielding quantitative serum concentrations of C1-INH that are approximately 20–40% of normal. Type 2 HAE accounts for approximately 15% of cases. Mutations of one of the amino acids near the active site of the inhibitor lead to synthesis of nonfunctional C1-INH protein and again less than half of the normal functioning protein. Patients with type 2 HAE have either normal or increased concentrations of the protein and low values in assays of C1-INH function.

A clinical syndrome resembling HAE and termed type 3 HAE has been described that affects mostly women and has a tendency to cause fewer abdominal attacks and more upper airway attacks. In this condition, no abnormalities of complement or of C1-INH have been described. Approximately 20% of affected patients have been found to have a gain-of-function abnormality of clotting factor XII, but the fundamental cause is still unknown.

The FDA has approved purified C1-INH for prophylaxis to prevent attacks. Androgens like the gonadotropin inhibitor danazol were previously used to prevent attacks. Weak androgens have many side effects that preclude their use in some patients. Their use in children is problematic because of the possibility of premature closure of the epiphyses, and these agents are not used in pregnant women. The fibrinolysis inhibitor ε-aminocaproic acid is also effective in preventing attacks and has been used in children, but its use was attended by the development of severe fatigue and muscle weakness over time.

In 2008, the FDA approved, for adolescents and older, the use of purified C1-INH (Cinryze), prepared from human plasma given intravenously for prophylaxis of this disease following clinical trials. The half-life of this plasma protein is relatively short, on the order of 40 hr, and the approved regimen is 1,000 units given twice a week. In 2009, a similar purified C1-inhibitor product, Berinert, used as 20 units/kg intravenously, was approved for the treatment of acute attacks. A recombinant C1-INH product has been approved for treatment of acute attacks in Europe, but is not currently approved for treatment in the United States. In 2009, a kallikrein inhibitor, ecallantide, given subcutaneously, was approved by the FDA for acute treatment in patients age 16 yr and older. This 60 amino acid peptide causes anaphylaxis in the rare patient, and is approved to be given only by medical personnel. In 2010, a bradykinin type 2 receptor antagonist, icatibant was approved for acute treatment in patients age 18 yr and older. All treatments are most effective when given early in an attack, and begin to have noticeable effect after about 1–4 hr after treatment.

Chapter 149

Anaphylaxis

Hugh A. Sampson, Julie Wang, and Scott H. Sicherer

Anaphylaxis is defined as a serious allergic reaction that is rapid in onset and may cause death. Anaphylaxis in children, particularly infants, is underdiagnosed. Anaphylaxis occurs when there is a sudden release of potent biologically active mediators from mast cells and basophils, leading to cutaneous (urticaria, angioedema, flushing), respiratory (bronchospasm, laryngeal edema), cardiovascular (hypotension, dysrhythmias, myocardial ischemia), and gastrointestinal (nausea, colicky abdominal pain, vomiting, diarrhea) symptoms (Table 149-1).

ETIOLOGY

The most common causes of anaphylaxis in children are different for hospital and community settings. Anaphylaxis occurring in the hospital results primarily from allergic reactions to medications and latex. Food allergy is the most common cause of anaphylaxis occurring outside the hospital, accounting for about half of the anaphylactic reactions reported in pediatric surveys from the United States, Italy, and South Australia (Table 149-2). Peanut allergy is an important cause of food-induced anaphylaxis, accounting for the majority of fatal and near-fatal reactions. In the hospital, latex is a particular problem for children undergoing multiple operations, such as patients with spina bifida and urologic disorders, and has prompted many hospitals to switch to latex-free products. Patients with latex allergy may also experience food-allergic reactions from homologous proteins in foods such as bananas, kiwi, avocado, chestnut, and passion fruit. Anaphylaxis to galactose-α-1,3-galactose has been reported 3-6 hr after eating meat.

EPIDEMIOLOGY

The overall annual incidence of anaphylaxis in the United States is estimated at 50 cases/100,000 persons/yr, totaling >150,000 cases/yr, with the highest rate for the pediatric age group (0-19 yr) at 70/100,000 persons/yr. An Australian parental survey found that 0.59% of children 3-17 yr of age had experienced at least 1 anaphylactic event. Having asthma and the severity of asthma are important anaphylaxis risk factors (Table 149-3).

PATHOGENESIS

Principal pathologic features in fatal anaphylaxis include acute bronchial obstruction with pulmonary hyperinflation, pulmonary edema, intraalveolar hemorrhaging, visceral congestion, laryngeal edema, and urticaria and angioedema. Acute hypotension is attributed to vasomotor dilation and/or cardiac dysrhythmias.

Most cases of anaphylaxis are believed to be the result of activation of mast cells and basophils via cell-bound allergen-specific

*In the pediatric population, some anaphylaxis triggers, such as hormones (progesterone), seminal fluid, and occupational allergens, are uncommon, as is idiopathic anaphylaxis.

1Exercise with or without a cotrigger, such as a food or medication, cold air, or cold water.

immunoglobulin (Ig) E molecules. Patients initially must be exposed to the responsible allergen to generate allergen-specific antibodies. In many cases, the child and the parent are unaware of the initial exposure, which may be from passage of food proteins in maternal breast milk or skin exposures. When the child is reexposed to the sensitizing allergen, mast cells and basophils, and possibly other cells, such as macrophages, release a variety of mediators (histamine, tryptase) and cytokines that can produce allergic symptoms in any or all target organs. Clinical anaphylaxis may also be caused by mechanisms other than IgE-mediated reactions, including direct release of mediators from mast cells by medications and physical factors (morphine, exercise, cold), disturbances of leukotriene metabolism (aspirin and nonsteroidal antiinflammatory drugs), immune aggregates and complement activation (blood products), probable complement activation (radiocontrast dyes, dialysis membranes), and IgG-mediated reactions (high-molecular-weight dextran, chimeric or humanized monoclonal antibodies) (see Table 149-2).

### CLINICAL MANIFESTATIONS AND DIAGNOSIS

The onset of symptoms may vary depending on the cause of the reaction. Reactions from ingested allergens (foods, medications) are delayed in onset (minutes to 2 hr) compared with those from injected allergens (insect sting, medications) and tend to have more gastrointestinal symptoms. Initial symptoms may include any of the following constellation of symptoms: pruritus about the mouth and face; a sensation of warmth, weakness, and apprehension (sense of doom); flushing, urticaria and angioedema, oral or cutaneous pruritus, tightness in the throat, dry staccato cough and hoarseness, perioral pruritus, nasal congestion, sneezing, dysnea, deep cough and wheezing; nausea, abdominal cramping, and vomiting, especially with ingested allergens; uterine contractions (manifesting as lower back pain); and faintness and loss of consciousness in severe cases. Some degree of obstructive laryngeal edema is typically encountered with severe reactions. Cutaneous symptoms may be absent in up to 20% of cases, and the acute onset of severe bronchospasm in a previously well asthmatic person should suggest the diagnosis of anaphylaxis. Sudden collapse in the absence of cutaneous symptoms should also raise suspicion of vasovagal collapse, myocardial infarction, arrhythmia, pulmonary embolism, or seizure disorder. Laryngeal edema, especially with abdominal pain, may also be a result of hereditary angioedema (see Chapter 148). Symptoms in infants may not be easy to identify (see Table 149-1).

### LABORATORY FINDINGS

Laboratory studies may indicate the presence of IgE antibodies to a suspected causative agent, but this result is not definitive. Plasma histamine is elevated for a brief period but is unstable and difficult to measure in a clinical setting. Plasma tryptase is more stable and remains elevated for several hours but often is not elevated, especially in food-induced anaphylactic reactions.

### DIAGNOSIS

A National Institutes of Health–sponsored expert panel has recommended an approach to the diagnosis of anaphylaxis (Table 149-4). The differential diagnosis includes other forms of shock (hemorrhagic, cardiogenic, septic), vasopressor reactions including flush syndromes such as carcinoid syndrome, excess histamine syndromes (systemic mastocytosis), ingestion of monosodium glutamate, scombroidosis, and hereditary angioedema. In addition, panic attack, vocal cord dysfunction, pheochromocytoma, and red man syndrome (caused by vancomycin) should be considered.

</table>

### Table 149-4 Diagnosis of Anaphylaxis

Anaphylaxis is highly likely when any 1 of the following 3 criteria is fulfilled:

1. Acute onset of an illness (minutes to several hours) with involvement of the skin and/or mucosal tissue (e.g., generalized hives, pruritus or flushing, swollen lips/tongue/uvula) and at least 1 of the following:
   - Respiratory compromise (e.g., dyspnea, wheeze/bronchospasm, stridor, reduced peak PEF, hypoxemia)
   - Reduced BP or associated symptoms of end-organ dysfunction (e.g., hypotonia [collapse], syncope, incontinence)
2. Two or more of the following that occur rapidly after exposure to a likely allergen for that patient (minutes to several hours):
   - Involvement of the skin/mucosal tissue (e.g., generalized hives, itch/flutter, swollen lips/tongue/uvula)
   - Respiratory compromise (e.g., dyspnea, wheeze/bronchospasm, stridor, reduced PEF, hypoxemia)
   - Reduced BP or associated symptoms (e.g., hypotonia [collapse], syncope, incontinence)
   - Persistent gastrointestinal symptoms (e.g., crampy abdominal pain, vomiting)
3. Reduced BP following exposure to known allergen for that patient (minutes to several hours):
   - Infants and children: low systolic BP (age-specific) or >30% drop in systolic BP
   - Adults: systolic BP <90 mm Hg or >30% drop from patient’s baseline

*Atopic diseases are a risk factor for anaphylaxis triggered by food, latex, and exercise, but not for anaphylaxis triggered by most drugs or by insect stings. *Patients taking β-adrenergic blockers or ACE inhibitors seem to be at increased risk for severe anaphylaxis. In addition, those taking β-adrenergic blockers may not respond optimally to epinephrine treatment and may need glucagon, a polypeptide with non-catecholamine-dependent inotropic and chronotropic cardiac effects, atropine for persistent bradycardia, or ipratropium for persistent bronchospasm.

TREATMENT
Anaphylaxis is a medical emergency requiring aggressive management with intramuscular (first line) or intravenous epinephrine, intramuscular or intravenous H₁ and H₂ antihistamine antagonists, oxygen, intravenous fluids, inhaled β-agonists, and corticosteroids (Table 149-5, Fig. 149-1). The initial assessment should ensure an adequate airway with effective respiration, circulation, and perfusion. Epinephrine is the most important medication, and there should be no delay in its administration. Epinephrine should be given by the intramuscular route to the lateral thigh (1:1000 dilution, 0.01 mg/kg; max 0.5 mg). For children ≥12 yr, many recommend the 0.5 mg intramuscular dose. The intramuscular dose can be repeated 2 or 3 times at intervals of 5-15 min if an intravenous continuous epinephrine infusion has not yet been started and symptoms persist. The 1:10,000 dilution of epinephrine should be used for intravenous administration. If IV access is not readily available, then epinephrine can be administered via the endotracheal or intraosseous routes. Anaphylaxis refractory to repeated doses of epinephrine has anecdotally been treated with glucagon or methylene blue. The patient should be placed in a supine position and lower extremities elevated when there is concern for hemodynamic compromise. Fluids are also important in patients with shock. Other drugs (antihistamines, glucocorticosteroids) have a secondary role in the management of anaphylaxis. Patients may experience biphasic anaphylaxis, which occurs when anaphylactic symptoms recur after apparent resolution. The mechanism of this phenomenon is unknown, but it appears to be more common when therapy is initiated late and symptoms at presentation are more severe. It does not appear to be affected by the administration of corticosteroids during the initial therapy. More than 90% of biphasic responses occur within 4 hr, so patients should be observed for at least 4 hr before being discharged from the emergency department. Referrals should be made to appropriate specialists for further evaluation and follow-up.

Figure 149-1 Algorithm for the treatment of anaphylactic event in the outpatient setting. IV, Intravenous. (From Lieberman P, Nicklas RA, Oppenheimer J, et al: The diagnosis and management of anaphylaxis practice parameter: 2010 update, J Allergy Clin Immunol 126:477–480 e471–442, 2010 [Fig. E2].)

IM, intramuscularly; IV, intravenously; PO, by mouth.
PREVENTION

For patients experiencing anaphylactic reactions, the triggering agent should be avoided and education regarding early recognition of anaphylactic symptoms and administration of emergency medications should be provided. Patients with food allergies must be educated in allergen avoidance, including active reading of food ingredient labels and knowledge of potential contamination and high-risk situations. Any child with food allergy and a history of asthma, peanut, tree nut, fish or shellfish allergy, or a previous anaphylactic reaction should be given an epinephrine autoinjector (Adrenaclick, Auvi-Q, EpiPen), liquid cetirizine (or alternatively, diphenhydramine), and a written emergency plan in case of accidental ingestion. A form can be downloaded from Food Allergy Research & Education at http://www.foodallergy.org.

In cases of food-associated exercise-induced anaphylaxis, children must not exercise within 2-3 hr of ingesting the triggering food and, like children with exercise-induced anaphylaxis, should exercise with a friend, learn to recognize the early signs of anaphylaxis (sensation of warmth and facial pruritus), stop exercising, and seek help immediately if symptoms develop. Children experiencing a systemic anaphylactic reaction including respiratory symptoms to an insect sting should be evaluated and treated with immunotherapy, which is more than 90% protective. Reactions to medications can be reduced and minimized by using oral medications in preference to injected forms and avoidance of cross-reacting medications. Low osmolarity radiocontrast dyes and pretreatment can be used in patients in whom previous reactions are suspected. The use of nonlatex gloves and materials should be used in children undergoing multiple operations. Any child who is at risk for anaphylaxis should receive emergency medications (including epinephrine autoinjector), education on identification of signs and symptoms of anaphylaxis and proper administration of medications, and a written emergency plan in case of accidental exposure, and encouraged to wear medical identification jewelry.

Chapter 149  ◆  Anaphylaxis  1136.e1

Bibliography

Serum sickness is a systemic, immune complex–mediated hypersensitivity vasculitis classically attributed to the therapeutic administration of foreign serum proteins or other medications (Table 150-1).

**ETIOLOGY**

Immune complexes involving heterologous (animal) serum proteins and complement activation are important pathogenic mechanisms in serum sickness. Antibody therapies derived from the horse or sheep are available for treatment of envenomation by the black widow spider and a variety of snakes, for treatment of botulism, and for immunosuppression (antithymocyte globulin). The availability of alternative medical therapies, modified or bioengineered antibodies, and biologics of human origin have supplanted the use of nonhuman antiserum, reducing the risk of serum sickness. A serum sickness–like reaction may be attributed to drug allergy, triggered by antibiotics (particularly cefaclor). In contrast to a true serum sickness, serum sickness–like reactions do not exhibit the immune complexes, hypocomplementemia, vasculitis, and renal lesions that are seen in serum sickness reactions.

**PATHOGENESIS**

Serum sickness is a classic example of a type III hypersensitivity reaction caused by antigen–antibody complexes. In the rabbit model using bovine serum albumin as the antigen, symptoms develop with the appearance of antibody against the injected antigen. As free antigen concentration falls and antibody production increases over days, antigen–antibody complexes of various sizes develop in a manner analogous to a precipitin curve. Whereas small complexes usually circulate harmlessly and large complexes are cleared by the reticuloendothelial system, intermediate-sized complexes that develop at the point of slight antigen excess may deposit in blood vessel walls and tissues. There the immune microprecipitates induce vascular (leukocytoclastic vasculitis with immune complex deposition) and tissue damage through activation of complement and granulocytes.

Complement activation (C3a, C5a) promotes chemotaxis and adherence of neutrophils to the site of immune complex deposition. The processes of immune complex deposition and of neutrophil accumulation may be facilitated by increased vascular permeability, owing to the release of vasoactive amines from tissue mast cells. Mast cells may be activated by binding of antigen to immunoglobulin (Ig) E or through contact with anaphylatoxins (C3a). Tissue injury results from the liberation of proteolytic enzymes and oxygen radicals from the neutrophils.

**CLINICAL MANIFESTATIONS**

The symptoms of serum sickness generally begin 7-12 days after injection of the foreign material, but may appear as late as 3 wk afterward. The onset of symptoms may be accelerated if there has been earlier exposure or previous allergic reaction to the same antigen. A few days before the onset of generalized symptoms, the site of injection may become edematous and erythematous. Symptoms usually include fever, malaise, and rashes. Urticaria and morbilliform rashes are the predominant types of skin eruptions. In a prospective study of serum sickness induced by administration of equine antithymocyte globulin, an initial rash was noted in most patients. It began as a thin serpiginous band of erythema along the sides of the hands, fingers, feet, and toes at the junction of the palmar or plantar skin with the skin of the dorsolateral surface. In most patients, the band of erythema was replaced with the appearance of antibody against the injected antigen.

*Based on review of most current literature. Other medications that are not listed are also cited to cause serum sickness.

---

by petechiae or purpura, presumably because of low platelet counts or local damage to small blood vessels. Additional symptoms include edema, myalgia, lymphadenopathy, symmetric arthralgia or arthritis involving multiple joints, and gastrointestinal complaints, including pain, nausea, diarrhea, and melena. Symptoms typically resolve within 2 wk of removal of the offending agent, although in unusual cases, symptoms can persist for as long as 2-3 mo.

Carditis, glomerulonephritis, Guillain-Barré syndrome, and peripheral neuritis are rare complications. Serum sickness–like reactions from drugs are characterized by fever, pruritus, urticaria, and arthralgias that usually begin 1-3 wk after drug exposure. The urticarial skin eruption becomes increasingly erythematous as the reaction progresses and can evolve into dusky centers with round plaques.

**DIFFERENTIAL DIAGNOSIS**
The differential diagnosis of serum sickness and serum sickness-like reactions includes viral illnesses with exanthems, hypersensitivity vasculitis, Kawasaki disease, acute rheumatic fever, acute meningococcal or gonococcal infection, endocarditis, systemic onset juvenile idiopathic arthritis (Still disease), Lyme disease, hepatitis and other types of drug reactions (see Chapter 152).

**DIAGNOSIS**
In most cases, the diagnosis of serum sickness is made clinically based upon the characteristic pattern of acute or subacute onset of a rash, fever, and severe arthralgia and myalgia disproportionate to the degree of swelling, occurring after exposure to a potential culprit.

The patients who appear moderately or severely ill, or who are not taking a medication that can be readily identified as the culprit, should be evaluated with the following laboratory tests:

- Complete blood count and differential; thrombocytopenia is often present.
- Erythrocyte sedimentation rate and C-reactive protein; erythrocyte sedimentation rate is usually elevated.
- Urinalysis; mild proteinuria, hemoglobinuria, and microscopic hematuria may be seen.
- Serum chemistries, including blood urea nitrogen, creatinine, and liver function tests.
- Complement studies, including CH50, C3, and C4; serum complement levels (C3 and C4) are generally decreased and reach a nadir at about day 10. C3a anaphylatoxin may be increased.
- Testing for specific infectious diseases, if indicated by the history or physical examination.
- Appropriate viral or bacterial cultures if an infection is suspected.
- Skin biopsies are not usually necessary for confirming the diagnosis, because the findings are variable and not specific for serum sickness. Direct immunofluorescence studies of skin lesions often reveal immune deposits of IgM, IgA, IgE, or C3.

**TREATMENT**
There are no evidence-based guidelines or controlled trials upon which to base therapy recommendations. Treatment is primarily supportive, consisting of discontinuation of the offending agent, antihistamines for pruritus, and nonsteroidal antiinflammatory agents and analgesics for low-grade fever and mild arthralgia. When the symptoms are especially severe, for example, fever >38.5°C (101.3°F), severe arthralgia or myalgia, or renal dysfunction, systemic corticosteroids can be used. Prednisone (1-2 mg/kg/day, max 60 mg/day) for 1-2 wk is usually sufficient. Once the offending agent is discontinued and depending on its half-life, symptoms resolve spontaneously in 1-4 wk. Symptoms lasting longer suggest another diagnosis.

**PREVENTION**
The primary mode of prevention of serum sickness is to seek alternative therapies. In some cases, non–animal-derived formulations may be available (human-derived botulinum immune globulin). Other alternatives are partially digested antibodies of animal origin and engineered (humanized) antibodies. The potential of these therapies to elicit serum sickness–like disease appears low. When only animal-derived antitoxin/antivenom is available, skin tests should be performed before administration of serum, but this procedure indicates the risk only of anaphylaxis, not of serum sickness. For patients who have evidence of anaphylactic sensitivity to horse serum, a risk-to-benefit assessment must be made to determine the need to proceed with treatment. If needed, the serum can usually be successfully administered by a process of rapid desensitization using protocols of gradual administration outlined by the manufacturers. Serum sickness is not prevented by desensitization or by pretreatment with corticosteroids.

Bibliography

Adverse reactions to foods consist of any untoward reaction following the ingestion of a food or food additive and are classically divided into food intolerances (e.g., lactose intolerance), which are adverse physiologic responses, and food allergies, which are adverse immunologic responses and can be immunoglobulin (Ig) E-mediated or non–IgE-mediated (Tables 151-1 to 151-3). Like other atopic disorders, food allergies appear to have increased over the past 3 decades, primarily in countries with a Western lifestyle. Worldwide, estimates of food allergy prevalence range from 1-10%; in the United States, food allergies affect an estimated 3.5% of the U.S. population. Up to 6% of children experience food allergic reactions in the 1st 3 yr of life, including approximately 2.5% with cow’s milk allergy, 1.5% with egg allergy, and 1% with peanut allergy. Peanut allergy prevalence tripled over the past decade. Most children “outgrow” milk and egg allergies, with approximately 50% doing so by school-age. In contrast, approximately 80-90% of children with peanut, nut, or seafood allergy retain their allergy for life.

**PATHOGENESIS**

Food intolerances are the result of a variety of mechanisms, whereas food allergy is predominantly caused by IgE-mediated and/or cell-mediated mechanisms. In susceptible individuals exposed to certain allergens, food-specific IgE antibodies are formed that bind to Fcε receptors on mast cells, basophils, macrophages, and dendritic cells. When food allergens penetrate mucosal barriers and reach cell-bound IgE antibodies, mediators are released that induce vasodilation, smooth muscle contraction, and mucus secretion, which result in symptoms of immediate hypersensitivity (allergy). Activated mast cells and macrophages may release several cytokines that attract and activate other cells, such as eosinophils and lymphocytes, leading to prolonged inflammation. Symptoms elicited during acute IgE-mediated reactions can affect the skin (urticaria, angioedema, flushing), gastrointestinal tract (oral pruritus, angioedema, nausea, abdominal pain, vomiting, diarrhea), respiratory tract (nasal congestion, rhinorrhea, nasal pruritus, sneezing, laryngeal edema, dyspnea, wheezing), and cardiovascular system (dysrhythmias, hypotension, loss of consciousness). In the other major form of food allergies, lymphocytes, primarily food allergen–specific T cells, secrete excessive amounts of various
Table 151-1  Adverse Food Reactions

| FOOD INTOLERANCE (NON–IMMUNE SYSTEM-MEDIATED, NONTOXIC, NONINFECTIONOUS) | Host factors | Gastrointestinal disorders—inflammatory bowel disease, irritable bowel syndrome, pseudoobstruction, colic
| | Idiosyncratic reactions—caffeine in soft drinks (“hyperactivity”) | Psychologic—food phobias, obsessive/compulsive disorder
| | Migraines (rare) | Other: pancreatic insufficiency (cystic fibrosis), peptic disease

**Food factors (toxic or infectious or pharmacologic)**

- Infectious organisms—Escherichia coli, Staphylococcus aureus, Clostridium perfringens, Shigella, botulism, Salmonella, Yersinia, Campylobacter
- Toxins—histamine (scombroid poisoning), saxitoxin (shellfish)
- Pharmacologic agents—caffeine, theobromine (chocolate, tea), tryptamine (tomatoes), tyramine (cheese), benzoic acid in citrus fruits (perioral flare)
- Contaminants—heavy metals, pesticides, antibiotics

**FOOD ALLERGY**

**IgE-mediated**

- Cutaneous—urticaria, angioedema, morbilliform rashes, flushing, contact urticarial
- Gastrointestinal—allergy syndrome, gastrointestinal anaphylaxis
- Respiratory—acute rhinoconjunctivitis, bronchospasm
- Generalized—anaphylactic shock, exercise induced anaphylaxis

**Mixed IgE- and non-IgE-mediated**

- Cutaneous—atopic dermatitis, contact dermatitis
- Gastrointestinal—food protein–induced enterocolitis, proctocolitis, enteropathy
- Respiratory—asthma

**Non–IgE-mediated**

- Cutaneous—contact dermatitis, dermatitis herpetiformis (celiac disease)
- Gastrointestinal—food protein–induced enterocolitis, proctocolitis, enteropathy
- Respiratory—food-induced pulmonary hemosiderosis (Heiner syndrome)
- Unclassified

---

Table 151-2  Differential Diagnosis of Adverse Food Reactions

| GASTROINTESTINAL DISORDERS (WITH VOMITING AND/OR DIARRHEA) | Structural abnormalities (pyloric stenosis, Hirschsprung disease, reflux) |
| Enzyme deficiencies (primary or secondary): | Disaccharidase deficiency—lactate, fructose, sucrose-isomaltase |
| Galactosemia | Malignancy with obstruction |
| Other: pancreatic insufficiency (cystic fibrosis), peptic disease |

**CONTAMINANTS AND ADDITIVES**

- Flavorings and preservatives—rarely cause symptoms:
  - Sodium metabisulfite, monosodium glutamate, nitrates
- Dyes and colorings—very rarely cause symptoms (urticaria, eczema): Tartrazine
- Toxins:
  - Bacterial, fungal ( aflatoxin), fish-related ( scombroid, ciguatera)
  - Infectious organisms:
    - Bacteria (Salmonella, Escherichia coli, Shigella)
    - Virus ( rotavirus, enterovirus)
    - Parasites ( Giardia, Akis simplex [in fish])
- Accidental contaminants:
  - Heavy metals, pesticides
  - Pharmacologic agents:
    - Caffeine, glycosidal alkaloid solanine ( potato spuds), histamine ( fish), serotonin ( banana, tomato), tryptamine ( tomato), tyramine ( cheese)

**PSYCHOLOGIC REACTIONS**

- Food phobias

*Recent studies suggest that resolution may occur at a later age, especially in children with multiple food allergies and lifetime peak food-specific IgE >50 kU/L.
†Fish allergy that is acquired in childhood can resolve.
‡Allergy to fresh apples, carrots, and peaches ( oral allergy syndrome) is commonly caused by heat-labile proteins. Fresh fruit causes oral pruritus, but cooked fruit is tolerated. There is generally no risk of anaphylaxis, although in rare cases, allergies to cross-reactive lipid transfer protein can cause anaphylaxis after ingestion of fruits (e.g., peach) and vegetables.

cytokines that lead to a “delayed,” more chronic inflammatory process affecting the skin (pruritus, erythematous rash), gastrointestinal tract (failure to thrive, early satiety, abdominal pain, vomiting, diarrhea), or respiratory tract (food-induced pulmonary hemorrhosis). Mixed IgE and cellular responses to food allergens can also lead to chronic disorders such as atopic dermatitis, asthma, and allergic eosinophilic esophagitis and gastroenteritis.

Children in whom IgE-mediated food allergies develop may be sensitized by food allergens penetrating the gastrointestinal barrier, referred to as class 1 food allergens, or by food allergens that are partially homologous to plant pollens penetrating the respiratory tract, referred to as class 2 food allergens. Any food may serve as a class 1 food allergen, but egg, milk, peanuts, tree nuts, fish, soy, and wheat account for 90% of food allergies during childhood. Many of the major allergenic proteins of these foods have been characterized. There is variable but significant cross-reactivity with other proteins within an individual food group. Exposure and sensitization to these proteins often occur very early in life. Virtually all milk allergies develop by 12 mo of age and all egg allergies by 18 mo of age, and the median age of first peanut allergic reactions is 14 mo. Because allergic reactions to these high-risk allergens occur in infancy, it was once thought that avoidance of these foods and delayed introduction to the diet would prevent allergy. Indeed, the opposite is probably true and delayed introduction of these foods actually increases the risk of allergy. Current recommendations are to introduce egg, peanut products, milk, wheat, and other allergenic foods after 4–6 mo of exclusive breast feeding (Table 151-4).

Class 2 food allergens are typically vegetable, fruit or nut proteins that are partially homologous with pollen proteins (see Table 151-3). With the development of seasonal allergic rhinitis from birch, grass, or ragweed pollens, subsequent ingestion of certain uncooked fruits or vegetables provokes the oral allergy syndrome. Intermittent ingestion of allergenic foods may lead to acute symptoms such as urticaria or anaphylaxis, whereas prolonged exposure may lead to chronic disorders such as atopic dermatitis and asthma. Cell-mediated sensitivity typically develops to class 1 allergens.

**CLINICAL MANIFESTATIONS**

From a clinical and diagnostic standpoint, it is most useful to subdivide food hypersensitivity disorders according to the predominant target organ (Table 151-5) and immune mechanism (see Table 151-1).

**Gastrointestinal Manifestations**

Gastrointestinal food allergies are often the first form of allergy to affect infants and young children and typically manifest as irritability, vomiting or “spitting-up,” diarrhea, and poor weight gain. Cell-mediated hypersensitivities without IgE involvement predominate, making standard allergy tests such as prick skin tests and in vitro tests for food-specific IgE antibodies of little diagnostic value.

**Food protein–induced enterocolitis syndrome** (FPIES) typically manifests in the first several months of life as irritability, intermittent vomiting and protracted diarrhea, and may result in dehydration (Table 151-6). Vomiting generally occurs 1–3 hr after feeding, and continued exposure may result in abdominal distention, bloody diarrhea, anemia, and failure to thrive. Symptoms are most commonly provoked by cow’s milk or soy protein–based formulas. A similar enterocolitis syndrome occurs in older infants and children from rice, oat, wheat, egg, peanut, nut, chicken, turkey, or fish. Hypotension occurs in approximately 15% of cases after allergen ingestion and may initially be thought to be caused by sepsis. FPIES usually resolves by age 3 yr.

**Food protein–induced proctocolitis** presents in the first few mo of life as blood-streaked stools in otherwise healthy infants (see Table 151-6). Approximately 60% of cases occur among breastfed infants, with the remainder largely among infants fed cow’s milk or soy products. Intermittent ingestion of uncooked fruits or vegetables provokes the oral allergy syndrome. Intermittent ingestion of allergenic foods may lead to acute symptoms such as urticaria or anaphylaxis, whereas prolonged exposure may lead to chronic disorders such as atopic dermatitis and asthma. Cell-mediated sensitivity typically develops to class 1 allergens.

*Eosinophilic gastroenteropathies encompass esophagitis, gastritis, gastroenterocolitis.
†If positive, may be a risk factor for persistent disease.
FPIES, food protein-induced enterocolitis syndrome.
protein–based formula. Blood loss is typically modest, but can occasionally produce anemia.

**Food protein–induced enteropathy** often manifests in the first several months of life as diarrhea, often with steatorrhea and poor weight gain (see Table 151-6). Symptoms include protracted diarrhea, vomiting in up to 65% of cases, failure to thrive, abdominal distention, early satiety, and malabsorption. Anemia, edema, and hypoproteinemia occur occasionally. **Cow’s milk sensitivity** is the most common cause of this food protein–induced enteropathy in young infants, but it has also been associated with sensitivity to soy, egg, wheat, rice, chicken, and fish in older children. **Celiac disease,** the most severe form of protein-induced enteropathy, occurs in about 1:100 of the U.S. population, although it may be “silent” in many patients (see Chapter 338.2). The full-blown form is characterized by extensive loss of absorptive villi and hyperplasia of the crypts, leading to malabsorption, chronic diarrhea, steatorrhea, abdominal distention, flatulence, and weight loss or failure to thrive. Oral ulcers and other extraintestinal symptoms secondary to malabsorption may occur. Genetically susceptible individuals (HLA-DQ2 or HLA-DQ8) demonstrate a cell-mediated response to tissue transglutaminase deamidated gliadin (a fraction of gluten), which is found in wheat, rye, and barley.

**Eosinophilic esophagitis** (EoE) may appear from infancy through adolescence, more frequently in boys (see Chapter 324). In young children, it is primarily cell mediated and manifests as chronic gastroesophageal reflux, intermittent emesis, food refusal, abdominal pain, dysphagia, irritability, sleep disturbance, and failure to respond to conventional reflux medications. EoE is a clinicopathologic diagnosis. The diagnosis is confirmed when 15 eosinophils per high-power field are seen on esophageal biopsy during treatment with proton pump inhibitors. **Eosinophilic gastroenteritis** occurs at any age and causes symptoms similar to those of EoE as well as prominent weight loss or failure to thrive, both of which are the hallmarks of this disorder. More than 50% of patients with this disorder are atopic, however food-induced IgE-mediated reactions have been implicated only in a minority of patients. Generalized edema secondary to hypoalbuminemia may occur in some infants with marked protein-losing enteropathy.

**Oral allergy syndrome** (pollen-associated food allergy syndrome) is an IgE-mediated hypersensitivity that occurs in many older children with birch and ragweed pollen-induced allergic rhinitis. Symptoms are usually confined to the oropharynx and consist of the rapid onset of oral pruritus, tingling and angioedema of the lips, tongue, palate, and throat, and occasionally a sensation of pruritus in the ears and tightness in the throat. Symptoms are generally short lived and are caused by local mast cell activation following contact with fresh fruit and vegetable proteins that cross-react with birch pollen (apple, carrot, potato, celery, hazel nuts, kiwi, cherry, pear), grass pollen (pumpkin, tomato, watermelon, kiwi), and ragweed pollen (banana, melons such as watermelon and cantaloupe).

**Acute gastrointestinal allergy** generally manifests as acute abdominal pain and vomiting that accompany IgE-mediated allergic symptoms in other target organs.

**Skin Manifestations**

Cutaneous food allergies are also common in infants and young children.

**Atopic dermatitis** is a form of eczema that generally begins in early infancy and is characterized by pruritus, a chronically relapsing course, and association with asthma and allergic rhinitis (see Chapter 145. Although not often apparent from history, at least 30% of children with moderate to severe atopic dermatitis have food allergies. The younger the child and the more severe the eczema, the more likely food allergy is playing a pathogenic role in the disorder. **Acute urticaria and angioedema** are among the most common symptoms of food allergic reactions (see Chapter 148). The onset of symptoms may be very rapid, within minutes after ingestion of the responsible allergen. Symptoms result from activation of IgE-bearing mast cells by food allergens that are absorbed and circulated rapidly throughout the body. Foods most commonly incriminated in children include egg, milk, peanuts, and nuts, although reactions to various seeds (sesame, poppy) and fruits (kiwi) are becoming more common. Chronic urticaria and angioedema are rarely caused by food allergies.

**Perioral dermatitis** is often a contact dermatitis caused by substances in toothpaste, gums, lipstick, to medications. **Perioral flushing** is often noted in infants fed citrus fruits and may be caused by benzoic acid in the food. It may also occur during nursing. In both situations, it is benign. Flushing may also be caused by urticulotemporal nerve (Frey) syndrome (familial, forceps delivery), which resolves spontaneously.

**Respiratory Manifestations**

Respiratory food allergies are uncommon as isolated symptoms. Although many parents believe that nasal congestion in infants is often caused by milk allergy, studies show this not to be the case. **Food-induced rhinoconjunctivitis** symptoms typically accompany allergic symptoms in other target organs, such as skin, and consist of typical allergic rhinitis symptoms (periocular pruritus and tearing, nasal congestion, and pruritus, sneezing, rhinorrhea). Wheezing occurs in approximately 25% of IgE-mediated food allergic reactions, but only approximately 10% of asthmatic patients have food-induced respiratory symptoms.

**Anaphylaxis**

Anaphylaxis is defined as a serious, multisystem allergic reaction that is rapid in onset and potentially fatal. Food allergic reactions are the single most common cause of anaphylaxis seen in hospital emergency departments in the United States. In addition to the rapid onset of cutaneous, respiratory, and gastrointestinal symptoms, patients may demonstrate cardiovascular symptoms, including hypotension, vascular collapse, and cardiac dysrhythmias, which are presumably caused by massive mast cell–mediator release. **Food-associated exercise-induced anaphylaxis** occurs more frequently among teenage athletes, especially females (see Chapter 149).

**DIAGNOSIS**

A thorough medical history is necessary to determine whether a patient’s symptomatology represents an adverse reaction (see Table 151-2), whether the adverse food reaction is an intolerance or food allergic reaction, and if the latter, whether it is likely to be an IgE-mediated or a cell-mediated response (Fig. 151-1). The following facts should be established: (1) the food suspected of provoking the reaction and the quantity ingested, (2) the interval between ingestion and the development of symptoms, (3) the types of symptoms elicited by the ingestion, (4) whether ingesting the suspected food produced similar symptoms on other occasions, (5) whether other inciting factors, such as exercise, are necessary, and (6) the interval from the last reaction to the food.

Prick skin tests and in vitro laboratory tests are useful for demonstrating IgE sensitization, defined as presence of food-specific IgE antibodies. Many fruits and vegetables require prick-prick skin testing with fresh produce because labile proteins are destroyed during commercial preparation. A negative skin test result virtually excludes an IgE-mediated form of food allergy. Conversely, the majority of children with positive skin test responses to a food do not react when the food is ingested, so more definitive tests, such as qualitative IgE tests or food elimination and challenge, are often necessary to establish a diagnosis of food allergy. Serum food-specific IgE levels ≥15 kU/L for milk (≥5 kU/L for children ≤1 yr), ≥27 kU/L for egg (≥25 kU/L for children <2 yr), and ≥14 kU/L for peanut are associated with a >95% likelihood of clinical reactivity to these foods in children with suspected reactivity. In the absence of a clear history of reactivity to a food and evidence of food-specific IgE antibodies, definitive studies must be performed before recommendations are made for avoidance or the use of highly restrictive diets that may be nutritionally deficient, logistically impractical, disruptive to the family, expensive, and a potential source of future feeding disorders. IgE-mediated food allergic reactions are generally very food specific, so the use of broad exclusionary diets, such as avoidance of all legumes, cereal grains, or animal products, is not warranted (Tables 151-3 and 151-7).

and may prevent the development of allergies later in life. Use of partially hydrolyzed whey formulas may be beneficial if breast feeding cannot be continued for 4-6 mo or after weaning, especially to prevent eczema in high risk families, but his approach remains controversial. Probiotic supplements may also reduce the incidence and severity of eczema. Because some skin preparations contain peanut oil, which may sensitize young infants, especially those with cutaneous inflammation, such preparations should be avoided.

There are no laboratory studies to help identify foods responsible for cell-mediated reactions. Consequently, elimination diets followed by food challenges are the only way to establish the diagnosis. Allergists experienced in dealing with food allergic reactions and able to treat anaphylaxis should perform food challenges. Before a food challenge is initiated, the suspected food should be eliminated from the diet for 10-14 days for IgE-mediated food allergy and up to 8 wk for some cell-mediated disorders, such as EoE. Some children with cell-mediated reactions to cow’s milk do not tolerate hydrolysate formulas and must receive amino acid-derived formulas. If symptoms remain unchanged despite appropriate elimination diets, it is unlikely that food allergy is responsible for the child’s disorder.

### TREATMENT

Appropriate identification and elimination of foods responsible for food hypersensitivity reactions are the only validated treatments for food allergies. Complete elimination of common foods (milk, egg, soy, wheat, rice, chicken, fish, peanut, nuts) is very difficult because of their widespread use in a variety of processed foods. The lay organization Food Allergy Research and Education (FARE, www.foodallergy.org) provides excellent information to help parents deal with both the practical and emotional issues surrounding these diets. Validated educational materials are also available through the Consortium of Food Allergy Research (www.cofargroup.org). Children with asthma and IgE-mediated food allergy, peanut or nut allergy, or a history of a previous severe reaction should be given self-injectable epinephrine and a written emergency plan in case of accidental ingestion (see Chapter 149). Because many food allergies are outgrown, children should be reevaluated periodically by an allergist to determine whether they have lost their clinical reactivity. A number of clinical trials are beginning to evaluate the efficacy of oral, sublingual, and epicutaneous (patch) immunotherapy for the treatment of IgE-mediated food allergies (milk, egg, peanut). Combining oral immunotherapy with anti-IgE treatment (omalizumab) may be even more effective than oral immunotherapy alone. Furthermore, extensively heated milk or egg in baked products are tolerated by the majority of milk and egg allergic children. Regular ingestion of baked products with milk and egg appears to accelerate resolution of milk and egg allergy. Management of egg-allergic children who require immunizations is noted in Table 151-8.

### PREVENTION

There is no consensus as to whether food allergies can be prevented. At present there is insufficient evidence to support the practice of restricting the maternal diet during pregnancy or breastfeeding or of delaying introduction of various allergenic foods to infants from atopic families (see Table 151-4). Exclusive breastfeeding for the first 4-6 mo of life may reduce allergic disorders in the first few years of life in infants at high risk for development of allergic disease. Potentially allergenic foods (eggs, milk, wheat, soy, peanut and tree nut products, fish) should be introduced after this period of exclusive breastfeeding and may prevent the development of allergies later in life. Use of partially hydrolyzed whey formulas may be beneficial if breast feeding cannot be continued for 4-6 mo or after weaning, especially to prevent eczema in high risk families, but his approach remains controversial. Probiotic supplements may also reduce the incidence and severity of eczema. Because some skin preparations contain peanut oil, which may sensitize young infants, especially those with cutaneous inflammation, such preparations should be avoided.

Adverse drug reactions can be divided into predictable (type A) and unpredictable reactions (type B). Predictable drug reactions, including drug toxicity, drug interactions, and adverse effects, are dose dependent, can be related to known pharmacologic actions of the drug, and occur in patients without any unique susceptibility. Unpredictable drug reactions are dose independent, often are not related to the pharmacologic actions of the drug, and occur in patients who are genetically predisposed. These include idiosyncratic reactions, allergic (hypersensitivity) reactions, and pseudoallergic reactions. Allergic reactions require prior sensitization, manifest as signs or symptoms characteristic of an underlying allergic mechanism such as anaphylaxis or urticaria, and occur in genetically susceptible individuals. They can occur at doses significantly below the therapeutic range. Pseudoallergic reactions resemble allergic reactions but are caused by non-immunoglobulin (Ig) E-mediated release of mediators from mast cells and basophils. Drug-independent cross-reactive antigens can induce sensitization manifesting as drug allergy. Patients with cetuximab-induced anaphylaxis have IgE antibodies in pretreatment samples specific for galactose-α-1,3-galactose. Galactose-α-1,3-galactose is present on the antigen-binding portion of the cetuximab heavy chain and is similar to structures in the ABO blood group.
IgE by antigen causes the release of preformed and newly synthesized IgE antibodies that are bound to the surfaces of tissue mast cells and/or when a drug or drug metabolite interacts with preformed drug-specific IgE receptors as another class of drug hypersensitivity. In T-cell–mediated concept, suggests pharmacologic interactions of drugs with immune receptors, such as histamine and leukotrienes, that contribute to the clinical development of urticaria, bronchospasm, or anaphylaxis. Cytotoxic reactions involve IgG or IgM antibodies that recognize drug antigen on the cell membrane. In the presence of serum complement, the antibody-coated cell is either cleared by the monocyte–macrophage system or is destroyed. Examples are drug-induced hemolytic anemia and thrombocytopenia. Immune complex reactions are caused by soluble complexes of drug or metabolite in slight antigen excess with IgG or IgM antibodies. The immune complex is deposited in blood vessel walls and causes injury by activating the complement cascade, as seen in serum sickness. Clinical manifestations include fever, urticaria, rash, lymphadenopathy, and arthralgias. Symptoms typically appear 1–3 wk after the last dose of an offending drug and subside when the drug and/or its metabolite is cleared from the body. Delayed-type hypersensitivity reactions are mediated by drug-specific T lymphocytes. Sensitization usually occurs via the topical route of administration, resulting in allergic contact dermatitis. Commonly implicated drugs include neomycin and local anesthetics in topical formulations.

Certain adverse drug reactions, including drug fever and the morbilliform rash seen with use of ampicillin or amoxicillin in the setting of Epstein–Barr virus infection, are not easily classified. Studies point to the role of T cells and eosinophils in delayed maculopapular reactions to a number of antibiotics. The mechanisms of T-cell–mediated drug hypersensitivity are not well understood. A novel hypothesis, the p-i concept, suggests pharmacologic interactions of drugs with immune receptors as another class of drug hypersensitivity. In T-cell–mediated

allergic drug reactions, the specificity of the T-cell receptor that is stimulated by the drug may be directed to a cross-reactive major histocompatibility complex–peptide compound. This information suggests that even poorly reactive native drugs are capable of transmitting a stimulatory signal via the T-cell receptor, which activates T cells and results in proliferation, cytokine production, and cytotoxicity. Previous contact with the causative drug is not obligatory, and an immune mechanism should be considered as the cause of hypersensitivity, even in reactions that occur with first exposure. Such reactions have been described for radiocontrast media and neuromuscular blocking agents.

**Drug Metabolism and Adverse Reactions**

Most drugs and their metabolites are not immunologically detectable until they have become covalently attached to a macromolecule. This multivalent hapten–protein complex forms a new immunogenic epitope that can elicit T- and B-lymphocyte responses. The penicillins and related β-lactam antibiotics are highly reactive with proteins and can directly haptenate protein carriers, possibly accounting for the frequency of immune-mediated hypersensitivity reactions with this class of antibiotics.

Incomplete or delayed metabolism of some drugs can give rise to toxic metabolites. Hydroxylamine, a reactive metabolite produced by cytochrome P450 oxidative metabolism, may mediate adverse reactions to sulfonamides. Patients who are slow acetylators appear to be at increased risk (see Chapter 59). In addition, cutaneous reactions in patients with AIDS treated with trimethoprim-sulfamethoxazole, rifampin, or other drugs may be a result of glutathione deficiency resulting in toxic metabolites. Serum sickness–like reactions in which immune complexes have not been documented, which occur most commonly with cefaclor, may result from an inherited propensity for hepatic biotransformation of drugs into toxic or immunogenic metabolites.

**Risk Factors for Hypersensitivity Reactions**

Risk factors for adverse drug reactions include prior exposure, previous reactions, age (20-49 yr), route of administration (parenteral or topical), dose (high), and dosing schedule (intermittent), as well as genetic predisposition (slow acetylators). Atopy does not appear to predispose patients to allergic reactions to low-molecular-weight compounds, but atopic patients in whom an allergic reaction develops have a significantly increased risk of serious reaction. Atopic patients also appear to be at greater risk for pseudoallergic reactions induced by radiocontrast media. Pharmacogenomics has an important role in identifying individuals at risk for certain drug reactions (see Chapter 59).

**DIAGNOSIS**

An accurate medical history is an important first step in evaluating a patient with a possible adverse drug reaction. Suspected drugs need to be identified along with dosages, route of administration, previous exposures, and dates of administration. In addition, underlying hepatic or renal disease may influence drug metabolism. A detailed description of past reactions may yield clues to the nature of the adverse drug reaction. The propensity for a particular drug to cause the suspected reaction can be checked with information in *Physicians’ Desk Reference, Drug Erption Reference Manual*, or directly from the drug manufacturer. It is important to remember, however, that the history may be unreliable, and many patients are inappropriately labeled as being drug allergic. This label can result in inappropriate withholding of a needed drug or class of drugs. In addition, relying solely on the history can lead to overuse of drugs reserved for special indications, such as vancomycin in patients in whom penicillin allergy is suspected. Approximately 90% of patients with a clinical history of penicillin allergy do not have evidence of penicillin-specific IgE antibodies on testing.

Skin testing is the most rapid and sensitive method of demonstrating the presence of IgE antibodies to a specific allergen. It can be performed with high-molecular-weight compounds, such as foreign antisera, hormones, enzymes, and toxoids. Reliable skin testing can also be performed with penicillin, but not with most other antibiotics. Most immunologically mediated adverse drug reactions are caused by metabolites rather than by parent compounds, and the metabolites for most drugs other than penicillin have not been defined. In addition, many metabolites are unstable or must combine with larger proteins to be useful for diagnosis. Testing with nonstandardized reagents requires caution in interpretation of both positive and negative results, because some drugs can induce nonspecific irritant reactions. Whereas a wheal-and-flare reaction is suggestive of drug-specific IgE antibodies, a negative skin test result does not exclude the presence of such antibodies because the relevant immunogen may not have been used as the testing reagent.

A positive skin test response to the major or minor determinants of penicillin has a 60% positive predictive value for an immediate hypersensitivity reaction to penicillin. In patients in whom skin test responses to the major and minor determinants of penicillin are negative, 97-99% (depending on the reagents used) tolerate the drug without an immediate reaction. At present, the major determinant of penicillin testing reagent PrePen (benzylpenicilloyl-polylysine) in the United States is available, but the minor determinant mixture has not been approved by the FDA as a testing reagent. Limited studies utilizing serum tests for IgE to β-lactams suggest high specificity (97-100%) but low sensitivity (29-68%). The positive and negative predictive values of skin testing for antibiotics other than penicillin are not well established. Nevertheless, positive immediate hypersensitivity skin test responses to nonirritant concentrations of nonpenicillin antibiotics may be interpreted as a presumptive risk of an immediate reaction to such agents.

Results of direct and indirect Coombs tests are often positive in drug-induced hemolytic anemia. Assays for specific IgG and IgM have been shown to correlate with a drug reaction in immune cytopenia, but in most other reactions, such assays are not diagnostic. In general, many more patients express humoral or T-cell immune responses to drug determinants than express clinical disease. Serum tryptase is elevated with systemic mast cell degranulation and can be seen with drug-associated mast cell activation, although it is not pathognomonic for drug hypersensitivity, and nonovulatory tryptase values can be seen in well-defined anaphylaxis.

**TREATMENT**

Specific desensitization, which involves the progressive administration of an allergen to render effector cells less reactive, is reserved for patients with IgE antibodies to a particular drug for whom an alternative drug is not available or appropriate. Specific protocols for many different drugs have been developed. Desensitization should be performed in a hospital setting, usually in consultation with an allergist and with resuscitation equipment available at all times. Although mild complications, such as pruritus and rash, are fairly common and often respond to adjustments in the drug dose or dosing intervals and medications to relieve symptoms, more severe systemic reactions can occur. Oral desensitization may be less likely to induce anaphylaxis than parenteral administration. Pretreatment with antihistamines or corticosteroids is not usually recommended. It is important to recognize that desensitization to a drug is effective only while the drug continues to be administered and that after a period of interruption or discontinuation, hypersensitivity can recur.

Graded challenges based on the administration of a drug in an incremental fashion until a therapeutic dose is achieved can be attempted with drugs causing non–IgE-mediated reactions, including trimethoprim-sulfamethoxazole. Graded challenges in aspirin- or nonsteroidal antiinflammatory drug (NSAID)–intolerant patients, particularly those with respiratory reactions, can also be performed. Patients with severe non–IgE-mediated hypersensitivity reactions should not receive the predisposing agents even in the small amounts used for skin testing (see Table 152-2).

**β-Lactam Hypersensitivity**

Penicillin is a frequent cause of anaphylaxis and is responsible for the majority of all drug-mediated anaphylactic deaths in the United States.
Although IgE-mediated reactions may occur after administration of penicillin by any route, parenteral administration is more likely to cause anaphylaxis. If a patient requires penicillin and has a previous history suggestive of penicillin allergy, it is necessary to perform skin tests on the patient for the presence of penicillin-specific IgE, ideally with both the major and minor determinants of penicillin. Skin tests for minor determinants of penicillin are important because approximately 20% of patients with documented anaphylaxis do not demonstrate skin reactivity to the major determinant. The major determinant is commercially available (Pre-Pen). The minor determinant mixture is currently not licensed and is synthesized as a nonstandardized testing reagent at select academic centers. Penicillin G is often used as a substitute for the minor determinant mixture, and may have negative predictive value similar to testing with major and minor determinants. Patients should be referred to an allergist capable of performing appropriate testing. If the skin test response is positive to either major or minor determinants of penicillin, the patient should receive an alternative non–cross-reacting antibiotic. If administration of penicillin is deemed necessary, desensitization can be performed by an allergist in an appropriate medical setting. Skin testing for penicillin-specific IgE is not predictive for delayed-onset cutaneous, bullous, or immune complex reactions. In addition, penicillin skin testing does not appear to re sensitize the patient.

Other β-lactam antibiotics, including semisynthetic penicillins, cephalosporins, carbacephems, and carbapenems, share the β-lactam ring structure. Patients with late-onset morbilliform rashes with amoxicillin are not considered to be at risk for IgE-mediated reactions to penicillin and do not require skin testing before penicillin administration. Many patients with Epstein-Barr virus infections treated with ampicillin or amoxicillin can experience a nonpruritic rash. Similar reactions occur in patients who receive allopurinol as treatment for elevated uric acid or have chronic lymphocytic leukemia. If the rash to ampicillin or amoxicillin is urticarial or systemic or the history is unclear, the patient should undergo penicillin skin testing if a penicillin is needed. There have been reports of antibodies specific for semisynthetic penicillin side chains in the absence of β-lactam ring–specific antibodies, although the clinical significance of such side chain–specific antibodies is unclear.

Varying degrees of in vitro cross-reactivity have been documented between cephalosporins and penicillins. Although the risk of allergic reactions to cephalosporins in patients with positive skin test responses to penicillin appears to be low (<2%), anaphylactic reactions have occurred after administration of cephalosporins in patients with a history of penicillin anaphylaxis. If a patient has a history of penicillin allergy and requires a cephalosporin, skin testing for major and minor determinants of penicillin should preferably be performed to determine whether the patient has penicillin-specific IgE antibodies. If skin test results are negative, the patient can receive a cephalosporin with no greater risk than found in the general population. If skin test results are positive for penicillin, recommendations may include: administration of an alternative antibiotic; cautious graded challenge with appropriate monitoring, with the recognition that there is a 2% chance of inducing an anaphylactic reaction; and desensitization to the required cephalosporin. Cross-reactivity is most likely when the cephalosporin shares the same side chain as the penicillin (Table 152-3).

Conversely, patients who require penicillin and have a history of an IgE-mediated reaction to a cephalosporin should also undergo penicillin skin testing. Patients with a positive result can receive penicillin. Patients with a positive result should either receive an alternative medication or undergo desensitization to penicillin. In patients with a history of allergic reaction to one cephalosporin who require another cephalosporin, skin testing with the required cephalosporin can be performed, with the recognition that the negative predictive value of such testing is unknown. If the skin test response to the cephalosporin is positive, the significance of the test should be checked further in control subjects to determine whether the positive response is IgE-mediated or an irritant response. The drug can then be administered by graded challenge or desensitization.

Carbapenems (imipenem, meropenem) represent another class of β-lactam antibiotics with a bicyclic nucleus that demonstrate a high degree of cross-reactivity with penicillins, although prospective studies suggest incidence of cross-reactivity on skin testing of approximately 1%. In contrast to β-lactam antibiotics, monobactams (aztreonam) have a monocyclic ring structure. Aztreonam-specific antibodies have been shown to be predominantly side chain–specific; data suggest that aztreonam can be safely administered to most penicillin-allergic subjects. On the other hand, administration of aztreonam to a patient with cefazidime allergy may be associated with increased risk of allergic reaction owing to similarity of side chains.

### Sulfonamides

The most common type of reaction to sulfonamides is a maculopapular eruption often associated with fever that occurs after 7-12 days of therapy. Immediate reactions, including anaphylaxis, as well as other immunologic reactions, have also been suggested. Hypersensitivity reactions to sulfonamides occur with much greater frequency in HIV-infected individuals. For patients in whom maculopapular rashes develop after sulfonamide administration, both graded challenge and desensitization protocols have been shown to be effective. These regimens should not be used in individuals with a history of Stevens-Johnson syndrome (SJS) or toxic epidermal necrolysis (TEN). Hyper-sensitivity reactions to sulfasalazine used for treatment of inflammatory bowel disease appear to result from the sulfapyridine moiety. Slow desensitization over >1 mo permits tolerance of the drug in many patients. In addition, oral and enema forms of 5-aminosalicylic acid, thought to be the pharmacologically active agent in sulfasalazine, are effective alternative therapies.

### Stevens-Johnson Syndrome and Toxic Epidermal Necrolysis

Blistering mucocutaneous disorders induced by drugs encompass a spectrum of reactions, including SJS and TEN (see Chapters 654.2 and 654.3). Epidermal detachment of <10% is suggestive of SJS, 30% detachment suggests TEN, and 10-30% detachment suggests overlap of the 2 syndromes. The features of SJS include confluent purpuric macules on face and trunk and severe, explosive mucosal erosions, usually at more than 1 mucosal surface, accompanied by fever and constitutional symptoms. Ocular involvement may be particularly severe, and the liver, kidneys, and lungs may also be involved. TEN, which appears to be related to keratinocyte apoptosis, manifests as

widespread areas of confluent erythema followed by epidermal necrosis and detachment with severe mucosal involvement. The risk of infection and mortality are high. Skin biopsy differentiates subepidermal cleavage characteristic of TEN from intraepidermal cleavage characteristic of the scalded-skin syndrome induced by staphylococcal toxins. TEN must be treated in a burn unit. Corticosteroids are contraindicated because they can significantly increase the risk of infection. High intravenous doses of immunoglobulin have been shown to be beneficial in patients with TEN, likely because of inhibition of Fas-mediated keratinocyte cell death by naturally occurring Fas-blocking antibodies in the intravenous immunoglobulin preparation.

**Hypersensitivity to Antiretroviral Agents**
A growing number of adverse drug reactions have been observed with antiretroviral agents, including reverse transcriptase inhibitors, protease inhibitors, and fusion inhibitors. Hypersensitivity to abacavir is a well-recognized, multiorgan, potentially life-threatening reaction that occurs in HIV-infected children. The reaction is independent of dose, with onset generally within 9-11 days of initiation of drug therapy. Rechallenge can be accompanied by significant hypotension and potential mortality (rate of 0.03%), and thus hypersensitivity to abacavir is an absolute contraindication for any subsequent use. Prophylaxis with prednisolone does not appear to prevent hypersensitivity reactions to abacavir. Importantly, genetic susceptibility appears to be conferred by the HLA-B*5701 allele, with a positive predictive value of >70% and a negative predictive value of 95-98%. Genetic screening would be cost-effective in white populations but not in populations of African or Asian descent, in which HLA-B*5701 allele frequency is <1%.

**Chemotherapeutic Agents**
Hypersensitivity reactions to chemotherapeutic drugs have been described, including to monoclonal antibodies. Rapid desensitization to a variety of unrelated agents, including carboplatin, paclitaxel, and rituximab, can be safely achieved in a 12-step protocol. Of note, this approach appears to be successful in both IgE-mediated and non–IgE-mediated reactions.

**Biologics**
An increasing number of biologic agents have become available for the treatment of autoimmune, allergic, cardiovascular, infectious, and neoplastic diseases. Their use may be associated with a variety of adverse reactions, including hypersensitivity reactions. Given the occurrence of anaphylaxis, including cases with delayed onset and protracted progression in spontaneous postmarketing adverse event reports, the FDA issued a boxed warning regarding risk of anaphylaxis and need for patient monitoring with use of omalizumab (see Chapter 144).

**Vaccines**
Measles-mumps-rubella vaccine has been shown to be safe in egg-allergic patients (although rare reactions to gelatin or neomycin can occur). The ovalbumin content in influenza vaccine is generally low and the majority of egg-allergic patients tolerate the vaccine. Skin testing with the influenza vaccine is not recommended for egg-allergic patients, but may be helpful if allergy to the vaccine itself is suspected. Egg-allergic patients should be given the injectable, not the live intranasal vaccine and be observed for 30 min after vaccination, in a setting prepared to treat anaphylaxis. For those with egg-allergic reactions resulting in more than urticaria, administration by an allergist is recommended.

**Perioperative Agents**
Anaphylactoid (non–IgE-mediated anaphylaxis) reactions occurring during general anesthesia may be caused by induction agents (thiopental) or muscle-relaxing agents (succinylcholine, pancuronium). Quaternary ammonium muscle relaxants (succinylcholine) can act as bivalent antigens in IgE-mediated reactions. Negative skin test results do not necessarily predict that a drug will be tolerated. Latex allergy should always be considered in the differential diagnosis of a perioperative reaction.

**Local Anesthetics**
Adverse drug reactions associated with local anesthetic agents are primarily toxic reactions resulting from rapid drug absorption, inadvertent intravenous injection, or overdose. Local anesthetics are classified as esters of benzoic acid (group I) or amides (group II). Group I includes benzocaine and procaine; group II includes lidocaine, bupivacaine, and mepivacaine. In suspected local anesthetic allergy, skin testing followed by a graded challenge can be performed or an anesthetic agent from a different group can be used.

**Insulin**
Insulin use has been associated with a spectrum of adverse drug reactions, including local and systemic IgE-mediated reactions, hemolytic anemia, serum sickness reactions, and delayed-type hypersensitivity. In general, human insulin is less allergenic than porcine insulin, which is less allergenic than bovine insulin, but for individual patients, porcine or bovine insulin may be the least allergenic. Patients treated with nonhuman insulin have had systemic reactions to recombinant human insulin even on the first exposure. More than 50% of patients who receive insulin develop antibodies against the insulin preparation, although there may not be any clinical manifestations. Local cutaneous reactions usually do not require treatment and resolve with continued insulin administration, possibly owing to IgG-blocking antibodies. More severe local reactions can be treated with antihistamines or by splitting the insulin dose between separate administration sites. Local reactions to the protamine component of neutral protamine Hagedorn insulin may be avoided by switching to Lente insulin. Immediate-type reactions to insulin, including urticaria and anaphylactic shock, are unusual and almost always occur after reinitiation of insulin therapy in sensitized patients. Insulin therapy should not be interrupted if a systemic reaction to insulin occurs and continued insulin therapy is essential. Skin testing may identify a less-antigenic insulin preparation. The dose following a systemic reaction is usually reduced to one-third, and successive doses are increased in 2-5 unit increments until the dose resulting in glucose control is attained. Insulin skin testing and desensitization are required if insulin treatment is subsequently interrupted for more than 24-48 hr. Immunologic resistance usually occurs when high titers of predominantly IgG antibodies to insulin develop. A rare form of insulin resistance caused by circulating antibodies to tissue insulin receptors is associated with acanthosis nigricans and lipodystrophy. Coexisting insulin allergy may be present in up to a third of patients with insulin resistance. Approximately half of affected patients benefit from substitution with a less-reactive insulin preparation, based on skin testing.

**Drug-Induced Hypersensitivity Syndrome**
Drug-induced hypersensitivity syndrome, also referred to as DRESS (drug rash with eosinophilia and systemic symptoms) syndrome, is a potentially life-threatening syndrome that has been described primarily with anticonvulsants, although many other medications have been implicated (see Tables 152-1 and 152-2). It is characterized by fever, maculopapular rash, facial edema, eosinophilia, generalized lymphadenopathy, and potentially life-threatening damage of 1 or more organs, usually renal or hepatic. Onset is delayed, usually weeks after initiation of the medication. It has been associated with reactivation of human herpesvirus 6. Treatment is withdrawal of the medication, systemic steroids, and supportive care, but symptoms can worsen or persist for weeks to months after the drug has been discontinued.

**Red Man Syndrome**
Red man syndrome is caused by nonspecific histamine release and is most commonly described with administration of intravenous vancomycin. It can be prevented by slowing the vancomycin infusion rate or by preadministration of H1-blockers.

**Radiocontrast Media**
Anaphylactoid reactions to radiocontrast media or dye can occur after intravascular administration and during myelograms or retrograde pyelograms. No single pathogenic mechanism has been defined, but it
is likely that mast cell activation accounts for the majority of these reactions. Complement activation has also been described. There is no evidence that sensitivity to seafood or iodine predisposes to radiocontrast media reactions. Predictive tests are not available. Patients who have atopic profiles, who are using β-blockers, and who have had prior anaphylactoid reactions are at increased risk. Other diagnostic alternatives should be considered, or patients can be given low-osmolality radiocontrast media with a pretreatment regimen including oral prednisone, diphenhydramine, and albuterol, with or without cimetidine or ranitidine.

**Narcotic Analgesics**

Opiates such as morphine and related narcotics can induce direct mast cell degranulation. Patients may experience generalized pruritus, urticaria, and occasionally, wheezing. If there is a suggestive history and analgesia is required, a nonnarcotic medication should be considered. If this intervention does not control pain, graded challenge with an alternative opiate is an option.

**Aspirin and Nonsteroidal Antiinflammatory Drugs**

Aspirin and NSAIDs can cause anaphylactoid reactions or urticaria and/or angioedema in children, and, rarely, asthma with or without rhinoconjunctivitis in adolescents. There is no skin or in vitro test to identify patients who may react to aspirin or other NSAIDs. Once aspirin or NSAID intolerance has been established, options include avoidance and pharmacologic desensitization and subsequent continued treatment with aspirin or NSAIDs, if indicated. A number of studies suggest that cyclooxygenase-2 inhibitors are tolerated by the majority of patients with NSAID-induced adverse reactions.

Joint Task Force on Practice Parameters; American Academy of Allergy, Asthma and Immunology; American College of Allergy, Asthma, and Immunology;
Rheumatic diseases are defined by the constellation of results of the physical examination, autoimmune marker and other serologic tests, tissue pathology, and imaging. Defined diagnostic criteria exist for most rheumatic diseases. Recognition of clinical patterns remains essential for diagnosis because there is no single diagnostic test and results may be positive in the absence of disease. Further complicating the diagnosis, children sometimes present with partial criteria that evolve over time or with features of more than one rheumatic disease (overlap syndromes). The primary mimics of rheumatic diseases are infection and malignancy but also include metabolic, orthopedic, and chronic pain conditions. Exclusion of possible mimicking disorders is essential before initiation of treatment for a presumptive diagnosis, especially corticosteroids. After careful evaluation has excluded non-rheumatic causes, referral to a pediatric rheumatologist for confirmation of the diagnosis and treatment should be considered.

**SYMPTOMS SUGGESTIVE OF RHEUMATIC DISEASE**

There are no classic symptoms of a rheumatic disease, but common symptoms include joint pain, fever, fatigue, and rash. Presenting signs and symptoms help direct the evaluation and limit unnecessary testing. Once a differential diagnosis is developed on the basis of history and physical findings, a directed assessment assists in determining the diagnosis.

Arthralgias are common in childhood and are a frequent reason for referral to pediatric rheumatologists. Arthralgias without physical findings for arthritis suggest infection, malignancy, orthopedic conditions, benign syndromes, or pain syndromes such as fibromyalgia (Table 153-1). Although rheumatic diseases may manifest as arthralgias, arthritis is a stronger predictor of the presence of rheumatic disease and a reason for referral to a pediatric rheumatologist. The timing of joint pain along with associated symptoms including poor sleep and interference with normal activities provides important clues. Poor sleep, debilitating generalized joint pain that worsens with activity, school absences, and normal physical and laboratory findings in an adolescent suggest a pain syndrome (e.g., fibromyalgia). If arthralgia is accompanied by a history of dry skin, hair loss, fatigue, growth disturbance, and/or cold intolerance, testing for thyroid disease is merited. Nighttime awakenings because of severe pain along with decreased platelet count or white blood cell count or, alternatively, a very high white blood cell count, may lead to the diagnosis of malignancy, especially narrow-occupying lesions such as acute lymphocytic leukemia and neuroblastoma. Pain with physical activity suggests a mechanical problem such as an overuse syndrome or orthopedic condition. An adolescent girl presenting with knee pain aggravated by walking up stairs and on patellar distraction likely has patellofemoral syndrome. Children ages 3 to 10 yr who have a history of episodic pain that occurs at night after increased daytime physical activity that is relieved by rubbing, but who have no limp or complaints in the morning, likely have growing pains. There is often a positive family history for growing pains, which may aid in this diagnosis. Intermittent pain in a child, especially a girl age 3 to 10 yr, that is increased with activity and is associated with hyperextensible joints on exam is likely benign hypermobility syndrome. Many febrile illnesses cause arthralgias that improve when the temperature normalizes, and arthralgias are part of the diagnostic criteria for acute rheumatic fever (ARF; see Chapter 183.1). Arthralgia may also be a presenting symptom of pediatric systemic lupus erythematosus (SLE) and chronic childhood arthritis such as juvenile idiopathic arthritis (JIA). Interestingly, many children with JIA do not complain of joint symptoms at presentation. Other symptoms more suggestive of arthritis include morning stiffness, joint swelling, limited range of motion, pain with joint motion, gait disturbance, fever, and fatigue and/or stiffness after physical inactivity (gelling phenomenon). A diagnosis of chronic juvenile arthritis cannot be made without the finding of arthritis on physical examination (see Chapters 155 and 156), and there are no laboratory tests diagnostic of juvenile rheumatoid arthritis or any other chronic inflammatory arthritis in childhood.

Fatigue is a nonspecific symptom that may point to the presence of a rheumatic disease but is also common in nonrheumatic causes such as viral infections, pain syndromes, depression, and malignancy. Fatigue, rather than the specific complaints of muscle weakness, is a common presenting complaint in juvenile dermatomyositis (JDM). It is also commonly present in SLE, vasculitis, and the chronic childhood arthritides. Overwhelming fatigue with inability to attend school is more suggestive of chronic fatigue syndrome, pediatric fibromyalgia, or other amplified pain syndrome.

**SIGNS SUGGESTIVE OF RHEUMATIC DISEASE**

A complete physical examination is mandated in any child in whom a rheumatic disease is suspected, because many rheumatic diseases have associated subtle physical findings that will further refine the differential diagnosis. In addition, many rheumatic diseases have multisystem effects, and a stepped assessment should focus on delineating the extent of organ system involvement (e.g., skin, joints, muscle, hepatic, renal, cardiopulmonary).

Presence of a photosensitive malar rash that spares the nasolabial folds is suggestive of SLE (Table 153-2; see Fig. 158-1A), especially in an adolescent girl. Diffuse facial rash is more indicative of JDM. A hyperkeratotic rash on the face or around the ears of an adolescent African-American girl may represent discoid lupus (see Fig. 158-1D). A palpable purpuric rash on the extensor surfaces of the lower extremities points to Henoch-Schönlein purpura (see Fig. 167-1A). Less localized purpuric rashes and petechiae are present in systemic vasculitis or blood dyscrasias including coagulopathies. Nonblanching erythematous papules on the palms are seen in vasculitis and SLE. Gottron papules (see Fig. 159-2) and heliotrope rashes (see Fig. 159-1) along with erythematous rashes on the elbows and knees are pathognomonic of JDM. Dilated capillary loops in the nail beds (periungual telangiectasias; see Fig. 159-3) are common in JDM, scleroderma, and secondary Raynaud phenomenon. An evanescent macular rash associated with fever is part of the diagnostic criteria for systemic onset arthritis (see Fig. 155-12). Sun sensitivity or photosensitive rashes are indicative of SLE or JDM but can also be caused by antibiotics.

Mouth ulcers are part of the diagnostic criteria for SLE and Behcet disease (see Fig. 158-1D); painless nasal ulcers and erythematous macules on the hard palate are also common in SLE. Cartilage loss in the nose, causing a saddle nose deformity, is classically present in granulomatosis with polyangiitis (formally Wegener granulomatosis; see Fig. 167-4) but is also seen in relapsing polychondritis and syphilis.
Alopecia can be associated with SLE but is also found in localized scleroderma (see Fig. 160-4) and JDM. Raynaud phenomenon may be a primary benign idiopathic disorder or can be a presenting complaint in the child with scleroderma, lupus, mixed connective tissue disease (MCTD), or an overlap syndrome. Diffuse lymphadenopathy is present in many rheumatic diseases, including SLE, polyarticular JIA, and systemic JIA. Irregular pupils may represent the insidious and unrecognized onset of uveitis associated with juvenile arthritis. Erythematosus conjunctiva may be a result of uveitis or episcleritis associated with juvenile rheumatoid arthritis, SLE, sarcoidosis, spondyloarthropathies, or vasculitis.

A pericardial rub and orthoepnea are suggestive of pericarditis, often seen in systemic JIA, SLE, and sarcoid. Coronary artery dilation is strongly suggestive of Kawasaki disease but may also be a finding in systemic arthritis and other forms of systemic vasculitis. Interstitial lung disease, suggested by dyspnea on exertion or the finding of basilar rales with decreased carbon monoxide diffusion capacity, occurs in SLE, MCTD, and systemic sclerosis. Signs consistent with pulmonary hemorrhage points to Wegener granulomatosis, microscopic angiitis, or SLE. Pulmonary vascular aneurysms are indicative of Behçet disease.

Arthritis is defined by the presence of intraarticular swelling or 2 or more of the following findings on joint examination: pain on motion, loss of motion, erythema, and heat. Arthritis is present in all of the chronic childhood arthritis syndromes, along with SLE, JDM, vasculitis, Behçet disease, sarcoidosis, Kawasaki disease, and Henoch-Schönlein purpura. Nonrheumatic causes of arthritis include malignancy, infections such as septic arthritis, Lyme disease, osteomyelitis, viral infections (such as rubella, hepatitis B, parvovirus B19), and postinfectious etiologies such as Epstein-Barr virus, ARF, and reactive arthritis. ARF typically involves a migratory (lasting hours to days), painful arthritis. Pain on palpation of long bones is suggestive of malignancy. Specific muscle testing for weakness should be performed in a child presenting with fatigue or difficulty with daily tasks, as both of these symptoms may be manifestations of muscle inflammation.

### LABORATORY TESTING
There are no specific screening tests for rheumatologic disease. Once a differential diagnosis is determined, appropriate testing can be performed (Tables 153-3 and 153-4). Initial studies are generally performed in standard local laboratories. Screening for specific autoantibodies can be performed in commercial laboratories, but confirmation of results in a tertiary care center immunology laboratory is often necessary.

One essential laboratory test for rheumatic disease assessment is the complete blood count, as it yields many diagnostic clues. Elevated white blood cell count is compatible with malignancy, infection, systemic JIA, and vasculitis. Leukopenia can be caused by postinfectious, especially viral, etiologies, SLE, or malignancy. Lymphopenia is more specific for SLE than is leukopenia. Platelets are acute-phase reactants and are therefore elevated with inflammatory markers. Exceptions are a bone marrow–occupying malignancy, such as leukemia or neuroblastoma, SLE, and early Kawasaki disease. Anemia is nonspecific and may

be caused by any chronic illness, but hemolytic anemia (positive Coombs test result) may point to SLE or MCTD. Rheumatoid factor is present in less than 10% of children with JIA and thus has poor sensitivity as a diagnostic tool; it may be elevated by infections such as endocarditis, tuberculosis, syphilis, viral infections (parvovirus B19, hepatitides B and C, mycoplasma) as well as primary biliary cirrhosis and malignancies. In a child with chronic arthritis, rheumatoid factor serves as a prognostic indicator.

Inflammatory markers (erythrocyte sedimentation rate, C-reactive protein level) are nonspecific and are elevated in infections and malignancies as well as rheumatic diseases. Their levels may also be normal in rheumatic diseases such as arthritis, scleroderma, and dermatomyositis. Inflammatory marker measurements are more useful in rheumatic diseases such as arthritis, scleroderma, and dermatomyositis.

IMAGING STUDIES

Plain radiographs are useful in evaluation of arthralgias and arthritis, as they offer reassurance in benign pain syndromes and their findings are often abnormal in malignancies, osteomyelitis, and long-standing chronic juvenile arthritis. Radionuclide bone scans help localize areas of abnormality in the patient with diffuse pains caused by osteomyelitis, neuroblastoma, chronic multifocal osteomyelitis, and systemic arthritis. MRI findings are abnormal in inflammatory myositis and suggest the optimal site for biopsy; MRI is more sensitive than plain radiographs in detecting the presence of early erosive arthritis and demonstrates increased joint fluid, synovial enhancement, and sequela of trauma with internal joint derangement. Cardiopulmonary evaluation is suggested for diseases commonly affecting the heart and

Chapter 154
Treatment of Rheumatic Diseases
Jeffrey A. Dvergsten, Esi Morgan-DeWitt, and C. Egla Rabinovich

Nonpharmacologic as well as pharmacologic interventions are often necessary to meet the desired goals of disease management. Optimal disease management requires family-centered care delivered by a multidisciplinary team of healthcare professionals providing medical, psychological, social, and school support. Rheumatologic conditions most often follow a course marked by flares and periods of remission, although some children have unremitting disease. The goals of treatment are to control disease, relieve discomfort, avoid or limit drug toxicity, prevent or reduce organ damage, and maximize the physical function and quality of life of affected children. Nonpharmacologic therapy is an important adjunct to medical management of rheumatic diseases. A key predictor of long-term outcome consists of early recognition and referral to a rheumatology team experienced in the specialized care of children with rheumatic diseases. Significant differences in outcome are seen after disease onset in patients with juvenile idiopathic arthritis (JIA) depending on whether referral to a pediatric rheumatology center was accomplished within 6 mo of onset.

PEDIATRIC RHEUMATOLOGY TEAMS AND PRIMARY CARE PHYSICIANS

The multidisciplinary pediatric rheumatology team (Table 154-1) offers coordinated services for children and their families. General principles of treatment include: early recognition of signs and symptoms of rheumatic disease with timely referral to rheumatology for prompt initiation of treatment; monitoring for disease complications and adverse effects of treatment; coordination of subspecialty care and rehabilitation services with communication of clinical information; and child- and family-centered chronic illness care, including self-management support, alliance with community resources, partnership with schools, resources for dealing with the financial burdens of disease, and connection with advocacy groups. Planning for transition to adult care providers needs to start in adolescence. Central to effective care is partnership with the primary care provider, who helps coordinate care, monitor compliance with treatment plans, ensure appropriate immunization, monitor for medication toxicities, and
THERAPEUTICS

A key principle of pharmacologic management of rheumatic diseases is that early disease control, striving for induction of remission, leads to less tissue and organ damage with improved short- and long-term outcomes. Medications are chosen from broad therapeutic classes on the basis of diagnosis, disease severity, anthropometrics, and adverse effect profile. Many drug therapies used do not have U.S. Food and Drug Administration (FDA) indications for pediatric rheumatic disorders. Laboratory monitoring for toxicity includes a complete blood count (CBC), serum creatinine, liver function tests (LFTs), and urinalysis. The most frequent adverse effects of NSAIDs in children are nausea, decreased appetite, and abdominal pain. Gastritis or ulceration occurs less frequently in children. Less-common adverse effects, occurring in ≤5% of children undergoing long-term NSAID therapy, include mood change, concentration difficulty that can simulate attention deficit disorder, sleepiness, irritability, headache, tinnitus, alopecia, anemia, elevated liver enzyme values, proteinuria, and hematuria. Certain agents (indomethacin) have a higher risk of toxicity than others (ibuprofen); naproxen has an intermediate risk. These NSAID-associated adverse effects reverse quickly once the medication is stopped. Additional rare NSAID-specific adverse reactions may also occur. Aseptic menigitis has been associated with ibuprofen, primarily in patients with lupus. Naproxen is more likely than other NSAIDs to cause a unique skin reaction called pseudoporphyria, which is characterized by small hypopigmented depressed scars occurring in areas of minor skin trauma, such as fingernail scratches. Pseudoporphyria is more likely to occur in fair-skinned individuals and on sun-exposed areas. If pseudoporphyria develops, the inciting NSAID should be discontinued because scars can persist for years or be permanent. NSAIDs should be used cautiously in patients with dermatomyositis or systemic vasculitis because of an increased frequency of GI ulceration with these disorders. Salicylates have been supplanted by other NSAIDs owing to the relative frequency of salicylate hepatotoxicity and the association with Reye syndrome.

The response to NSAIDs varies greatly among individual patients, but overall, 40-60% of children with JIA experience improvement in their arthritis with NSAID therapy. Patients may try several different NSAIDs for 6-wk trials before finding one that demonstrates clinical benefit. NSAIDs with longer half-lives or sustained-release formulations allow for once- or twice-daily dosing and improve compliance. Laboratory monitoring for toxicity includes a complete blood count (CBC), serum creatinine, liver function tests (LFTs), and urinalysis every 6-12 mo, though guidelines for frequency of testing are not established.

Nonbiologic Disease-Modifying Antirheumatic Drugs

Methotrexate (MTX), an antimetabolite, is a cornerstone of therapy in pediatric rheumatology because of its sustained effectiveness and relative low toxicity over prolonged periods of treatment. The mechanism of action low-dose MTX in arthritis is complex but is believed

</table>
to result from the inhibition of folate-dependent processes by MTX polyglutamates, primarily their effect on the enzyme 5-aminoimidazole-4-carboxamide ribonucleotide (AICAR) transformylase leading to an increase of extracellular adenosine and consequently, cyclic adenosine monophosphate, which inhibits the production of proinflammatory cytokines including tumor necrosis factor (TNF)-α and interleukin (IL)-1β and their downstream effects on lymphocyte activation and proliferation.

MTX has a central role in the treatment of arthritis, especially in children with polyarticular JIA. The response to oral MTX (10 mg/m² once a week) is better than the response to placebo (63% vs. 36%). Children who show no response to standard doses of MTX often do show response to higher doses (15 or 30 mg/m²/wk). Subcutaneous administration of MTX is similar in absorption and pharmacokinetic properties to intramuscular injection, with less pain. MTX is commonly used in treatment of MTX is similar in absorption and pharmacokinetic properties to intramuscular injection, with less pain. MTX is commonly used in treatment of juvenile dermatomyositis as a steroid-sparing agent, with efficacy in 70% of patients. It has also been used successfully with a dosage of 10-20 mg/m²/wk in patients with systemic lupus erythematosus (SLE) to treat arthritis, serositis, and rash.

Because of the lower dose used in treating rheumatic diseases, MTX is well tolerated by children with toxicity being milder and qualitatively different from that observed with treatment of neoplasms. In 8 published studies including 288 patients with JIA taking MTX, adverse effects included elevated liver enzyme values (15%), GI toxicity (13%), stomatitis (3%), headache (1-2%), and leukopenia, interstitial pneumonitis, rash, and alopecia (<1%). Hepatotoxicity observed among adults with rheumatoid arthritis treated with MTX has raised concern about similar problems in children. Analysis of liver biopsy specimens in children with JIA undergoing long-term MTX treatment has revealed occasional mild fibrosis and no evidence of even moderate liver damage. Children receiving MTX should be counseled to avoid alcohol, smoking, and pregnancy. Folic acid 1 mg daily is given as an adjunct to minimize adverse effects. Lymphoproliferative disorders have been reported in adults treated with MTX, primarily in association with Epstein-Barr virus infection. Regression of lymphoma may follow withdrawal of MTX.

Monitoring laboratory tests for MTX toxicity include CBC and LFTs at regular intervals, initially every 4 wk for the 1st 3 mo of treatment, then every 8-12 wk, with more frequent intervals after dosing adjustments or in response to abnormal values.

**Hydroxychloroquine**

Hydroxychloroquine sulfate is an antimalarial drug important in the treatment of SLE and dermatomyositis, particularly cutaneous manifestations of disease and to reduce lupus flares. It is not indicated to treat JIA because of lack of efficacy. The most significant potential adverse effect is retinal toxicity, which occurs rarely but results in irreversible color blindness or loss of central vision. Complete ophthalmologic examinations, including assessment of peripheral vision and color fields, are conducted at baseline and every 6-12 mo to screen for ocular hypertension, glaucoma, nerve damage, cataract, and infection.

Leflunomide
Leflunomide is a DMARD approved for treatment of rheumatoid arthritis that offers an alternative to MTX for treatment of JIA. MTX outperformed leflunomide for treatment of JIA in a randomized trial (at 16 wk, 89% of patients receiving MTX achieved a 30% response rate vs. 68% of those receiving leflunomide), although both drugs were effective. Dosing is oral, once daily, and weight based: 10 mg for children 10 to <20 kg, 15 mg for children 20-40 kg, and 20 mg for children >40 kg. Adverse reactions include paresthesias and peripheral neuropathy, GI intolerance, elevated liver transaminases and hepatic failure, cytopenias, alopecia, and teratogenesis. Leflunomide has a long half-life, and in cases in which discontinuation of the agent is required, a drug elimination protocol with cholestyramine may be indicated. Avoidance of pregnancy is essential. Monitoring laboratory tests include CBC, LFTs, every 4 wk for the 1st 6 mo of treatment, then every 8-12 wk.

Sulfasalazine
Sulfasalazine is used to treat children with polyarticular JIA oligoarticular JIA, and the peripheral arthritis and enthesitis associated with juvenile ankylosing spondylitis. In JIA, sulfasalazine 50 mg/kg/day (adult maximum: 3,000 mg/day) achieves greater improvement in joint inflammation, global assessment parameters, and laboratory parameters than placebo. More than 30% of sulfasalazine-treated patients withdraw from the treatment because of adverse effects, primarily GI irritation and skin rashes. Sulfasalazine is associated with severe systemic hypersensitivity reactions, including Stevens-Johnson syndrome. Sulfasalazine is generally considered contraindicated in children with active systemic JIA because of increased hypersensitivity reactions. Sulfasalazine should not be used in patients with sulfa or salicylate hypersensitivity or porphyria.

Mycophenolate Mofetil
Mycophenolate mofetil (MMF) is an immunosuppressive drug approved by the FDA for organ transplant rejection. In rheumatology, MMF is used primarily for treatment of lupus, uveitis, and autoimmune skin manifestations. In adult clinical trials, MMF was noninferior to cyclophosphamide for induction therapy of lupus nephritis, with a potential for less-adverse effects (infection, gonadal toxicity). Dosing is based on body surface area: 600 mg/m² orally twice daily, with maximum dosage limits varying by formulation and body surface area. The most common adverse reaction is GI intolerance. Infections, cytopenias, and secondary malignancies are among other adverse reactions reported.

Glucocorticoids
Glucocorticoids are given through oral, intravenous, ocular, topical, and intraarticular administration as part of treatment of rheumatic disease. Oral steroids are foundational treatment for moderate to severe lupus, dermatomyositis, and most forms of vasculitis; their long-term use is associated with a long list of well-described, dose-dependent complications, including linear growth suppression, Cushingoid features, osteoporosis, avascular necrosis, hypertension, impaired glucose tolerance, mood disturbance, and increased infection risk. Glucocorticoids should be tapered to the lowest effective dose over time, and DMARDS introduced as steroid-sparing agents.

Intravenous steroids have been used to treat severe, acute manifestations of systemic rheumatic diseases such as SLE, dermatomyositis, and vasculitis. The intravenous route allows for higher doses to obtain an immediate, profound antiinflammatory effect. Methylprednisolone, 10-30 mg/kg/dose up to a maximum of 1 g given over 1 hr daily for 1-5 days, is the intravenous preparation of choice. Although generally associated with fewer adverse effects than oral steroids, intravenously administered steroids are associated with significant and occasionally life-threatening toxicities, such as cardiac arrhythmia, acute hypertension, hypotension, hyperglycemia, shock, pancreatitis, and avascular necrosis.

Ocular steroids are prescribed by ophthalmologists as ophthalmologic drops or injections into the soft tissue surrounding the globe (sub–Tenon capsule injection) for active uveitis. Long-term ocular steroid use leads to cataract formation and glaucoma. Current ophthalmologic management has significantly decreased the frequency of blindness as a complication of JIA-associated uveitis.

Intraarticular steroids are being used with increasing frequency as initial therapy for children with oligoarticular JIA or as bridge therapy while awaiting efficacy of a DMARD in polyarticular disease. Most patients have significant clinical improvement within 3 days. Duration of response depends on steroid preparation used, joint affected, and arthritis subtype, with the anticipated response rate to knee injection being between 60% and 80% at 6 mo. Intraarticular administration may result in subcutaneous atrophy and hypopigmentation of the skin at the injection site, as well as subcutaneous calcifications along the needle track.

Biologic Agents
Biologic agents are proteins that have been engineered to target and modulate specific components of the immune system with the goal of decreasing the inflammatory response. Antibodies have been developed to target specific cytokines such as IL-1 and IL-6 or to interfere with specific immune cell function through depletion of B cells or suppression of T-cell activation (Table 154-3). The availability of these agents has dramatically increased the therapeutic options for treating rheumatoid disease recalcitrant to nonbiologic therapies and they are, in some instances, becoming first-line interventions. A primary concern regarding biologic therapy is that when use is combined with other immunosuppressants, risk of malignancy may be increased.

Tumor Necrosis Factor-α Antagonists
Currently, 2 TNF antagonists have an FDA indication for treatment of children with moderate to severe polyarticular JIA (etanercept and adalimumab). Etanercept is a genetically engineered fusion protein consisting of 2 identical chains of the recombinant extracellular TNF receptor monomer fused with the Fc domain of human immunoglobulin G. Etanercept binds both TNF-α and lymphotoxin-α (formerly CTLa, cytotoxic T lymphocyte–associated antigen; Ig, immunoglobulin; IL, interleukin; TNF, tumor necrosis factor.

called TNF-β) and inhibits their activity. Three fourths of children with active polyarticular JIA that fails to respond to MTX demonstrate response to etanercept after 3 mo of therapy. Dosing is 0.8 mg/kg subcutaneous weekly (maximum 50 mg/dose) or 0.4 mg/kg subcutaneously twice a week (maximum 25 mg/dose). Adalimumab is a fully human anti-TNF monoclonal antibody used alone or in combination with MTX. In a placebo-controlled withdrawal-design study, a children continuing to receive adalimumab were less likely to experience disease flares (43% vs. 71%) even if they were also taking MTX (37% vs. 65%). Adalimumab is administered subcutaneously every other week at a dose of 20 mg for children weighing 15-30 kg and 40 mg for those weighing >30 kg.

*Infliximab* is a chimeric mouse-human monoclonal antibody, was tested in a randomized controlled clinical trial for use in JIA but did not achieve study end points. However, it is FDA approved for pediatric inflammatory bowel disease and has been used “off label” for treatment of polyarticular JIA, uveitis, Behçet syndrome, and sarcoidosis. Two additional anti-TNF agents—*golimumab*, a human monoclonal antibody against TNF, and *certolizumab pegol*, a pegylated humanized antibody against TNF—have been approved by the FDA for rheumatoid arthritis in adults and are currently in pediatric trials.

The most common adverse reactions are injection-site reactions that diminish over time. TNF blockade is associated with an increased frequency of serious systemic infections, including sepsis, dissemination of latent tuberculosis, and invasive fungal infections in endemic areas. TNF blockade should not be initiated in subjects with history of chronic or frequent recurrent infections. Tuberculosis should be tested for prior to initiation of therapy with TNF antagonists. If test results are positive, antitubercular treatment must be administered before anti-TNF treatment can be started. There is a theoretically increased risk of malignancy with TNF-α antagonists, and there have been reports of development of lupus-like syndromes, leukocytoclastic vasculitis, interstitial lung disease, demyelinating syndromes, antibody formation to the drug, rashes, cytopenias, anaphylaxis, serum sickness, and other reactions. The benefit: risk profile appears favorable after a decade of experience with this therapeutic class; the safety of longer-term suppression of TNF function is unknown.

**Modulator of T-Cell Activation**

*Abatacept* is a selective inhibitor of T-cell costimulation resulting in T-cell anergy. It is FDA approved for treatment of moderate to severe polyarticular JIA. In a double-blind, randomized controlled withdrawal trial in children whose disease had not responded to DMARDs, 53% of placebo-treated patients, compared with 20% of abatacept-treated patients, experienced disease flares during the double-blind withdrawal period. The frequency of adverse events did not differ between the groups. Abatacept is administered IV every other week for 3 doses (<75 kg: 10 mg/kg/dose; 75-100 kg: 750 mg/dose; >100 kg: 1,000 mg/dose; maximum 1,000 mg/dose at 0, 2, and 4 wk) and then monthly thereafter.

**B-Cell Depletion**

*Rituximab* is a chimeric monoclonal antibody to the antigen CD20, a transmembrane protein on the surface of B-cell precursors and mature B lymphocytes. This antibody induces B-cell apoptosis and causes depletion of circulating and tissue-based B cells. Antibody production is not completely abrogated as plasma cells are not removed. Rituximab is licensed for treatment of B-cell non-Hodgkin lymphoma and is FDA approved for use in adult rheumatoid arthritis and idiopathic thrombocytopenic purpura but does not have a pediatric indication. Rituximab may also have a role in treatment of SLE, particularly its hematologic manifestations. Adverse events include serious infusion reactions, cytopenias, hepatitis B virus reactivation, hypogammaglobulinemia, infections, serum sickness, vasculitis, and a rare but fatal side effect, progressive multifocal leukoencephalopathy. Resistance to rituximab may develop over time in patients being treated for lymphoma. *Belimumab* is a human monoclonal antibody to B-lymphocyte stimulator that negatively affects B-cell proliferation, differentiation, and long-term survival. It was FDA-approved in March 2011 for treatment of SLE in adults and studies of long-term safety and efficacy are ongoing. Currently, belimumab is not FDA approved for use in pediatric SLE.

**Interleukin-1 Antagonists**

*Anakinra*, a recombinant form of the human IL-1 receptor antagonist, competitively inhibits binding of IL-1α and IL-1β to the natural receptor, interrupting the cytokine proinflammatory cascade. Anakinra has been approved for rheumatoid arthritis in adults. In meta-analyses of treatments for rheumatoid arthritis, anakinra was outperformed by TNF-α antagonists but has a special niche in pediatric rheumatology for treatment of systemic JIA (SoJIA) and other autoinflammatory syndromes, such as cryopyrin-associated periodic syndromes. The medication is dosed subcutaneously, 1-2 mg/kg, once daily. An IL-1β monoclonal antibody, *canakinumab* is FDA approved for use in cryopyrin-associated periodic syndromes dosed subcutaneously every 8 wk and SoJIA dosed subcutaneously every 4 wk. Adverse reactions include significant injection site reactions and increased bacterial infections.

**Interleukin-6 Receptor Antagonist**

*Tocilizumab*, an anti-IL-6 receptor antibody binding to both soluble as well as membrane-associated receptors. Tocilizumab has FDA approval for treatment of SoJIA and polyarticular JIA. Adverse reactions include transaminase and lipid elevations. Tocilizumab is given as an IV infusion every 2 (SoJIA) to 4 (polyarticular JIA) wk.

**Intravenous Immunoglobulin**

Intravenous immunoglobulin (IVIG) is thought to be beneficial in various clinical conditions. IVIG significantly improves the short- and long-term natural history of Kawasaki disease. Open studies have supported benefit for juvenile dermatomyositis, lupus-associated thrombocytopenia, and polyarticular JIA. IVIG is given as 1-2 g/kg/dose, administered once monthly. It has been occasionally associated with severe systemic allergic–like reactions and post-infusion aseptic meningitis (headache, stiff neck).

**Cytotoxics**

**Cyclophosphamide**

Cyclophosphamide requires metabolic conversion in the liver to its active metabolites, which alkylate the guanine in DNA, leading to immunosuppression by the inhibition of the S2 phase of mitosis. The subsequent decrease in numbers of T and B lymphocytes results in diminished humoral and cellular immune responses. Cyclophosphamide infusions (500-1,000 mg/m²) given monthly for 6 mo, and then every 3 mo for 12-18 mo, have been shown to reduce the frequency of renal failure in patients with lupus and diffuse proliferative glomerulonephritis. Open trials suggest efficacy in severe central nervous system lupus. Oral cyclophosphamide (1-2 mg/kg/day) is effective as induction treatment of severe antineutrophilic cytoplasmic antibody-associated vasculitis and other forms of systemic vasculitis as well as interstitial lung disease or pulmonary hemorrhage associated with rheumatic disease. Cyclophosphamide is a potent cytotoxic drug associated with significant toxicities. Potential short-term adverse effects include nausea, vomiting, anorexia, alopecia, mucositis, hemorrhagic cystitis, and bone marrow suppression. Long-term complications include an increased risk for sterility and cancer, especially leukemia, lymphoma, and bladder cancer. Thirty percent to 40% of adult women with lupus treated with intravenous cyclophosphamide become infertile; the risk of ovarian failure appears to be significantly lower in adolescent and premenarchal girls. Ovarian suppression with an inhibitor of gonadotropin-releasing hormone to preserve fertility is currently being studied.

**Other Drugs**

Azathioprine is sometimes used to treat antineutrophilic cytoplasmic antibody-associated vasculitis following induction therapy or to treat SLE. *Cyclosporine* has been used occasionally in the treatment of dermatomyositis on the basis of uncontrolled studies and is helpful in the
treatment of macrophage activation syndrome complicating SoJIA (see Chapter 155). There are case reports describing the successful use of thalidomide, or its analog lenalidomide, as treatment for SoJIA, inflammatory skin disorders, and Behçet disease. Several drugs commonly used in the past to treat arthritis are no longer part of standard treatment, including salicylates, gold compounds, and d-penicillamine.

Bibliography

Chapter 155
Juvenile Idiopathic Arthritis
Eveline Y. Wu, Angela R. Bryan, and C. Eglė Rabinovich

Juvenile idiopathic arthritis (JIA) is the most common rheumatic disease in children and one of the more common chronic illnesses of childhood. JIA represents a heterogeneous group of disorders all sharing the clinical manifestation of arthritis. The etiology and pathogenesis of JIA are largely unknown, and the genetic component is complex, making clear distinction among various subtypes difficult. As a result, several classification schemas exist, each with its own limitations. The former classification scheme of the American College of Rheumatology uses the term juvenile rheumatoid arthritis and categorizes the disease into 3 onset types (Table 155-1). Attempting to standardize nomenclature, The International League of Associations for Rheumatology (ILAR) proposed a different classification using the term JIA (Table 155-2), inclusive of all subtypes of chronic juvenile arthritis. We refer to the ILAR classification criteria; see Chapter 156 for enthesitis-related arthritis (ERA) and psoriatic JIA (Tables 155-3 and 155-4).

Epidemiology
The worldwide incidence of JIA ranges from 0.8-22.6/100,000 children per year, with prevalence ranges from 7-401/100,000. These wide-ranging numbers reflect population differences, particularly environmental exposure and immunogenetic susceptibility, along with variations in diagnostic criteria, difficulty in case ascertainment, and lack of population-based data. It is estimated that 300,000 children in the United States have arthritis, including 100,000 with a form of JIA. Oligoarthritis is the most common subtype (40-50%), followed by polyarthritis (25-30%) and systemic JIA (5-15%) (see Table 155-4). There is no sex predominance in systemic JIA (sJIA), but more girls than boys are affected in both oligoarticular (3:1) and polyarticular (5:1) JIA. The peak age at onset is between 2 and 4 yr for oligoarticular disease. Age of onset has a bimodal distribution in polyarthritis, with peaks at 2-4 yr and 10-14 yr. sJIA occurs throughout childhood with a peak between 1 and 5 yr.

Etiology
The etiology and pathogenesis of JIA are not completely understood, though both immunogenetic susceptibility and an external trigger are considered necessary. JIA is a complex genetic trait in which multiple genes may affect disease susceptibility. Variants in major histocompatibility complex (MHC) class I and class II regions have indisputably been associated with different JIA subtypes. Non-HLA candidate loci are also associated with JIA, including polymorphisms in the genes encoding protein tyrosine phosphatase nonreceptor 22 (PTPN22), tumor necrosis factor (TNF)-α, macrophage inhibitory factor, interleukin (IL)-6, and IL-1α. There is evidence that the IL-6 gene confers susceptibility to sJIA, with increased transmission of the −174G allele in patients older than 5 yr. Possible nongenetic triggers include bacterial and viral infections, enhanced immune responses to bacterial or mycobacterial heat shock proteins, abnormal reproductive hormone levels, and joint trauma.

Pathogenesis
JIA is an autoimmune disease associated with alterations in both humoral and cell-mediated immunity. T lymphocytes have a central role, releasing proinflammatory cytokines favoring a type 1 helper T-lymphocyte response. Studies of T-cell receptor expression confirm recruitment of T lymphocytes specific for synovial non–self antigens. B-cell activation, immune complex formation, and complement activation also promote inflammation. Inheritance of specific cytokine alleles may predispose to upregulation of inflammatory networks, resulting in systemic disease or more severe articular disease.

sJIA is characterized by dysregulation of the innate immune system with a lack of autoreactive T cells and autoantibodies. It therefore may be more accurately classified as an autoinflammatory disorder, more like familial Mediterranean fever, than the other subtypes of JIA. This theory is also supported by work demonstrating similar expression patterns of a phagocytic protein (S100A12) in sJIA and familial Mediterranean fever, as well as the same marked responsiveness to IL-1 inhibitors.

All these immunologic abnormalities cause inflammatory synovitis, characterized pathologically by villous hypertrophy and hyperplasia with hyperemia and edema of the synovial tissue. Vascular endothelial hyperplasia is prominent and is characterized by infiltration of mononuclear and plasma cells with a predominance of T lymphocytes (Fig. 155-1). Advanced and uncontrolled disease leads to pannus formation and progressive erosion of articular cartilage and contiguous bone (Figs. 155-2 and 155-3).

Clinical Manifestations
Arthritis must be present to make a diagnosis of any JIA subtype. Arthritis is defined by intraarticular swelling or the presence of 2 or more of the following signs: limitation of range of motion, tenderness or pain on motion, increased heat) in ≥1 joint.

<tr>
<th>CATEGORY</th>
<th>DEFINITION</th>
<th>EXCLUSIONS</th>
</tr>
</thead>
</table>
| Systemic          | Arthritis in ≥1 joint with, or preceded by, fever of at least 2 wk in duration that is documented to be daily (“quotidian”) for at least 3 days and accompanied by ≥1 of the following: 1. Evanescent (nonfixed) erythematous rash 2. Generalized lymph node enlargement 3. Hepatomegaly or splenomegaly or both 4. Serositis†                                                                 | a. Psoriasis or a history of psoriasis in the patient or a 1st-degree relative  
b. Arthritis in an HLA-B27–positive boy beginning after the 6th birthday  
c. Ankylosing spondylitis, enthesitis-related arthritis, sacroiliitis with inflammatory bowel disease, Reiter syndrome, or acute anterior uveitis, or a history of one of these disorders in a 1st-degree relative  
d. Presence of immunoglobulin M RF on at least 2 occasions at least 3 mo apart |
| Oligoarthritis    | Arthritis affecting 1-4 joints during the 1st 6 mo of disease. Two subcategories are recognized: 1. Persistent oligoarthritis—affecting ≤4 joints throughout the disease course 2. Extended oligoarthritis—affecting >4 joints after the 1st 6 mo of disease | a, b, c, d (above) plus e. Presence of systemic JIA in the patient |
| Polyarthritis (RF-negative) | Arthritis affecting ≥5 joints during the 1st 6 mo of disease; a test for RF is negative | a, b, c, d, e |
| Polyarthritis (RF-positive) | Arthritis affecting ≥5 joints during the 1st 6 mo of disease; ≥2 tests for RF at least 3 mo apart during the 1st 6 mo of disease are positive | a, b, c, e |
| Psoriatic arthritis | Arthritis and psoriasis, or arthritis and at least 2 of the following: 1. Dactylitis‡ 2. Nail pitting§ and onycholysis 3. Psoriasis in a 1st-degree relative | b, c, d, e |
| Enthesitis-related arthritis | Arthritis and enthesis,† or arthritis or enthesis with at least 2 of the following: 1. Presence of or a history of sacroiliac joint tenderness or inflammatory lumbosacral pain or both¶ 2. Presence of HLA-B27 antigen 3. Onset of arthritis in a male >6 yr old 4. Acute (symptomatic) anterior uveitis 5. History of ankylosing spondylitis, enthesitis-related arthritis, sacroiliitis with inflammatory bowel disease, Reiter syndrome, or acute anterior uveitis in a 1st-degree relative | a, d, e |
| Undifferentiated arthritis | Arthritis that fulfills criteria in no category or in ≥2 of the above categories. | |

RF, rheumatoid factor.

*Quotidian fever is defined as a fever that rises to 39°C (102.2°F) once a day and returns to 37°C (98.6°F) between fever peaks.
†Serositis refers to pericarditis, pleuritis, or peritonitis, or some combination of the 3.
‡Dactylitis is swelling of ≥1 digits, usually in an asymmetric distribution, that extends beyond the joint margin.
§A minimum of 2 pits on any 1 or more nails at any time.
¶Enthesitis is defined as tenderness at the insertion of a tendon, ligament, joint capsule, or fascia to bone.
*Inflammatory lumbosacral pain refers to lumbosacral pain at rest with morning stiffness that improves on movement.

ANA, antinuclear antibody; CRP, C-reactive protein; ESR, erythrocyte sedimentation rate; JIA, juvenile idiopathic arthritis; MAS, macrophage activation syndrome; MTX, methotrexate; NSAID, nonsteroidal antiinflammatory drug; RF, rheumatoid factor; TNF, tumor necrosis factor; WBC, white blood cell count.

Oligoarthritis is defined as involving ≤4 joints within the 1st 6 mo of disease onset, and often only a single joint is involved (see Table 155-4). It predominantly affects the large joints of the lower extremities, such as the knees and ankles (Fig. 155-4). Isolated involvement of upper extremity large joints is less common. Those in whom disease never develops in more than 4 joints are regarded as having persistent oligoarticular JIA, whereas evolution of disease in more than 4 joints after 6 mo changes the classification to extended oligoarticular JIA and is associated with a worse prognosis. Isolated involvement of the hip is almost never a presenting sign and suggests ERA (see Chapter 156) or a nonrheumatic cause. The presence of a positive antinuclear antibody (ANA) confers increased risk for asymptomatic anterior uveitis, requiring periodic slit-lamp examination (Table 155-5). ANA positivity may also be correlated with younger age at disease onset, female sex, asymmetric arthritis, and lower number of involved joints over time.

Polyarthritis is characterized by inflammation of ≥5 joints in both upper and lower extremities (Figs. 155-5 and 155-6). Rheumatoid factor (RF)–positive polyarthritis resembles the characteristic symmetric presentation of adult rheumatoid arthritis. Rheumatoid nodules on the extensor surfaces of the elbows, spine, and over the Achilles tendons, although unusual, are associated with a more severe course and almost exclusively occur in RF-positive individuals (Fig. 155-7). Micrognathia reflects chronic temporomandibular joint disease

Figure 155-5  Hands and wrists of a girl with polyarticular juvenile idiopathic arthritis, rheumatoid factor–negative. Notice the symmetric involvement of the wrists, metacarpophalangeal joints, and proximal and distal interphalangeal joints. In this photograph, there is cream with occlusive dressing on the patient’s right hand in preparation for placement of an intravenous line for administration of a biologic agent.

(Fig. 155-8). Cervical spine involvement (Fig. 155-9), manifesting as decreased neck extension, occurs with a risk of atlantoaxial subluxation and neurologic sequelae. Hip disease may be subtle, with findings of decreased or painful range of motion on exam (Fig. 155-10). sJIA is characterized by arthritis, fever, rash, and prominent visceral involvement, including hepatosplenomegaly, lymphadenopathy, and serositis (pericarditis). The characteristic fever, defined as spiking temperatures >39°C (102.2°F), occurs on a daily or twice-daily basis for at least 2 wk, with a rapid return to normal or subnormal temperatures (Fig. 155-11). The fever is often present in the evening and is frequently accompanied by a characteristic faint, erythematous, macular rash. The evanescent salmon-colored lesions, classic for sJIA, are linear or circular and are most commonly distributed over the trunk and proximal extremities (Fig. 155-12). The classic rash is nonpruritic and migratory with lesions lasting <1 hr. Koebner phenomenon, a cutaneous hyper-sensitivity in which classic lesions are brought on by superficial trauma, is often present. Heat can also evoke rash. Fever, rash, hepatosplenomegaly, and lymphadenopathy are present in >70% of affected children. Without arthritis, the differential diagnosis includes the episodic fever syndromes, infection, and malignancy. Some children initially present with only systemic features, and evolve over time, but definitive diagnosis requires presence of arthritis. Arthritis may affect any number of joints, but the course is classically polyarticular, may be very destructive, and can include hip, cervical spine, and temporomandibular joint involvement.

Macrophage activation syndrome (MAS) is a rare but potentially fatal complication of sJIA that can occur at any time (onset, medication change, active or remission) during the disease course. It is also referred to as secondary hemophagocytic syndrome or hemophagocytic lymphohistiocytosis (HLH) (see Chapter 307). There is increasing evidence that sJIA/MAS and HLH share similar functional defects in granule-dependent cytotoxic lymphocyte activity. MAS classically manifests as acute onset of high spiking fevers, lymphadenopathy, hepatosplenomegaly, and encephalopathy. Laboratory evaluation shows thrombocytopenia and leukopenia with elevated liver enzymes, lactate dehydrogenase, ferritin, and triglycerides. Patients may have purpura and mucosal bleeding, as well as elevated fibrin split product values and prolonged prothrombin and partial prothromboplastin times. The erythrocyte sedimentation rate (ESR) falls because of hypofibrinogenemia and hepatic dysfunction, a feature useful in distinguishing MAS from a flare of systemic disease (Table 155-6). Although finalized diagnostic criteria for MAS do not currently exist, the features that were decided by an international consensus panel as the most important indicators of MAS include a falling platelet count, extreme hyperferritinemia, evidence of macrophage hemophagocytosis in the bone marrow, increased liver enzymes, falling leukocyte count, persistent, continuous fever ≥38°C (100.4°F), falling ESR, hypofibrinogenemia, and hypertriglyceridemia. A relative change in laboratory values is likely more relevant in making an early diagnosis than are absolute normal values. The diagnosis is suggested by clinical criteria and is confirmed by bone marrow biopsy demonstrating hemophagocytosis (Table 155-6). Emergency treatment with high-dose intravenous methylprednisolone, cyclosporine, or anakinra may be effective. Severe cases may require therapy similar to that for primary HLH (see Chapter 307).

Bone mineral metabolism and skeletal maturation are adversely affected in children with JIA, regardless of subtype. Children with JIA have decreased bone mass (osteopenia), which appears to be associated with increased disease activity. Increased levels of cytokines such as TNF-α and IL-6, both key regulators in bone metabolism, have deleterious effects on bone within the joint as well as systemically in the axial and appendicular bones. Abnormalities of skeletal maturation become most prominent during the pubertal growth spurt.

DIAGNOSIS

JIA is a clinical diagnosis without any diagnostic laboratory tests. The meticulous clinical exclusion of other diseases and many mimics is therefore essential. Laboratory studies, including tests for ANA and RF, are only supportive or prognostic, and their results may be normal in patients with JIA (see Tables 155-1 to 155-4).

DIFFERENTIAL DIAGNOSIS

The differential diagnosis for arthritis is broad and a careful, thorough investigation for other underlying etiologies is imperative (Table 155-7). History, physical exam, laboratory tests, and radiography may help exclude other possible causes. Arthritis can be a presenting manifestation for any of the multisystem rheumatic diseases of childhood, including systemic lupus erythematosus (see Chapter 158), juvenile dermatomyositis (see Chapter 159), sarcoidosis (see Chapter 165), and...

In Cassiday JT, Petty RE, Laxer RM, et al, editors: Textbook of pediatric rheumatology, ed 6, Philadelphia, 2011, Saunders Elsevier, Fig. 15-5, p. 257.)

Figure 155-8 CT scan of the temporomandibular joint of a patient with juvenile idiopathic arthritis exhibiting destruction on the right.

the vasculitic syndromes (see Chapter 167). In scleroderma (see Chapter 160), limited range of motion as a consequence of sclerotic skin overlying a joint may be confused with sequelae from chronic inflammatory arthritis. Acute rheumatic fever is characterized by exquisite joint pain and tenderness, a remittent fever, and a migratory polyarthritis. Autoimmune hepatitis can also be associated with an acute arthritis.

Many infections are associated with arthritis, and a recent history of infectious symptoms may help make a distinction. Viruses, including parvovirus B19, rubella, Epstein-Barr virus, hepatitis B virus, and HIV,

can induce a transient arthritis. Arthritis may follow enteric infections (see Chapter 157). Lyme disease (see Chapter 222) should be considered in children with oligoarthritis living in or visiting endemic areas. Although a history of tick exposure, preceding flu-like illness, and subsequent rash should be sought, they are not always present. Monoarticular arthritis unresponsive to antiinflammatory treatment may be the result of chronic mycobacterial or other infection such as Kingella kingae, and the diagnosis is established by synovial fluid analysis or biopsy. Acute onset of fever and a painful, erythematous, hot joint suggests septic arthritis. Isolated hip pain with limited motion raises the possibility of supplicative arthritis (see Chapter 685), osteomyelitis (see Chapter 684), toxic synovitis, Legg-Calvé-Perthes disease, slipped capital femoral epiphysis, and chondrolysis of the hip (see Chapter 678).

Lower-extremity arthritis and tenderness over insertion of ligaments and tendons, especially in a boy, raises the possibility of ERA (see Chapter 156). Psoriatic arthritis can manifest as limited joint involvement in an unusual distribution (e.g., small joints of the hand and
ankle) years prior to onset of cutaneous disease. Inflammatory bowel disease may manifest as oligoarthritis, usually affecting joints in the lower extremities, as well as gastrointestinal symptoms, elevations in ESR, and microcytic anemia.

Many conditions present solely with arthralgias (i.e., joint pain). Hypermobility may cause joint pain, especially in the lower extremities. Growing pains should be suspected in a child between the ages of 4-12 yr complaining of leg pain in the evenings with normal investigative studies and no morning symptoms. Nocturnal pain also alerts to the possibility of a malignancy. An adolescent with missed school days may suggest a diagnosis of fibromyalgia (see Chapter 168).

Children with leukemia or neuroblastoma may have joint or bone pain resulting from malignant infiltration of the bone, synovium, or, more often, the bone marrow, sometimes mo before demonstrating lymphoblasts on peripheral blood smear. Physical examination may reveal no tenderness, a deeper pain with palpation of the bone, or pain out of proportion to exam findings. Malignant pain often awakens the child from sleep and may cause cytopenias. Because platelets are an acute-phase reactant, a high ESR with leukopenia and a low normal platelet count may also be a clue to underlying leukemia. In addition, the characteristic quotidian fever of sJIA is absent in malignancy. Bone marrow examination is necessary for diagnosis. Some diseases, such as cystic fibrosis, diabetes mellitus, and the glycogen storage diseases, have associated arthropathies (see Chapter 169). Swelling that extends beyond the joint can be a sign of lymphedema or Henoch-Schönlein purpura (see Chapter 515). A peripheral arthritis indistinguishable from JIA occurs in the humoral immunodeficiencies (see Chapter 124), such as common variable immunodeficiency and

X-linked agammaglobulinemia. Skeletal dysplasias associated with a degenerative arthropathy are diagnosed from their characteristic radiologic abnormalities.

Systemic onset of JIA often presents as an fever of unknown origin (see Chapter 177). Important considerations in the differential diagnosis include infections (endocarditis, brucellosis, cat scratch disease, Q fever, mononucleosis), autoinflammatory disease (see Chapter 163) malignancy (leukemia, lymphoma, neuroblastoma) and HLH (see Chapter 507.2).

LABORATORY FINDINGS

Hematologic abnormalities often reflect the degree of systemic or articular inflammation, with elevated white blood cell and platelet counts and a microcytic anemia. Inflammation may also cause elevations in ESR and C-reactive protein, although it is not unusual for both to be normal in children with JIA.

Elevated ANA titers are present in 40-85% of children with oligoarticular or polyarticular JIA, but are rare with sJIA. ANA seropositivity is associated with increased risk of chronic uveitis in JIA. Approximately 5-15% of patients with polyarticular JIA are seropositive for RF. Anti–cyclic citrullinated peptide antibody, like RF, is a marker of more aggressive disease. Both ANA and RF seropositivity can occur in association with transient events, such as viral infection.

Children with sJIA usually have striking elevations in inflammatory markers and white blood cell and platelet counts. Hemoglobin levels are low, typically in the range of 7-10 g/dL, with indices consistent with anemia of chronic disease. The ESR is usually high, except in MAS. Although immunoglobulin levels tend to be high, ANA and RF are uncommon. Ferritin values are typically elevated and can be markedly increased in MAS (>10,000 ng/mL). In the setting of MAS, all cell lines have the potential to decline precipitously owing to the consumptive process. A low or normal white blood cell count and/or platelet count in a child with active sJIA should raise concerns for MAS.

Early radiographic changes of arthritis include soft tissue swelling, periarticular osteopenia, and periosteal new-bone apposition around affected joints (Fig. 155-13). Continued active disease may lead to subchondral erosions, loss of cartilage, with varying degrees of bony destruction, and fusion. Characteristic radiographic changes in cervical spine, most frequently in the neural arch joints at C2-C3 (see Fig. 155-9) may progress to atlantoaxial subluxation. MRI is more sensitive than radiography to detect early changes (Fig. 155-14).

Figure 155-13 Early (6 mo duration) radiographic changes of juvenile idiopathic arthritis. Soft-tissue swelling and periosteal new bone formation appear adjacent to the 2nd and 4th proximal interphalangeal joints.

Figure 155-14 MRI of the wrist in a child with wrist arthritis. Image on the left shows multiple erosions of carpal bones. Image on the right, obtained after administration of gadolinium contrast agent, reveals uptake consistent with active synovitis.

TREATMENT

The goals of treatment are to achieve disease remission, prevent or halt joint damage, and foster normal growth and development. All children with JIA need individualized treatment plans, and management is tailored according to disease subtype and severity, presence of poor
prognostic indicators, and response to medications. Disease management also requires monitoring for potential medication toxicities (see Chapter 154).

Children with oligoarthritis often show partial response to nonsteroidal antiinflammatory drugs (NSAIDs), with improvement in inflammation and pain (Table 155-8). Those who have no or partial response after 4-6 wk of treatment with NSAIDs or who have functional limitations, such as joint contracture or leg-length discrepancy, benefit from injection of intraarticular corticosteroids. Triamcinolone hexacetonide is a long-lasting preparation that provides a prolonged benefit from injection of intraarticular corticosteroids. Triamcinolone acetonide is a short-acting preparation that provides short-term but more potent relief. naproxen, ibuprofen, and meloxicam are effective, with lower cost and no need for blood testing. Other medications with potential benefits include the NSAIDs diclofenac, indomethacin, and sulindac, and the COX-2 inhibitors rofecoxib and valdecoxib.

Disease-modifying antirheumatic drugs (DMARDs), methotrexate, leflunomide, and sulfasalazine are used to treat children with an inadequate response to NSAIDs alone or those who have failed to respond to low dose corticosteroids. These agents are usually started followed by the initiation of IL-1 or IL-6 antagonist therapy, which often induces a dramatic and rapid response. Patients with severe disease activity may go directly to anakinra. Canakinumab, an IL-1β inhibitor, and tocilizumab, an IL-6 receptor antagonist, are available for adjunctive therapy. It may take 6-12 wk to see the effects of methotrexate. Failure of methotrexate monotherapy warrants the addition of a biologic DMARD. Biologic medications that inhibit proinflammatory cytokines, such as TNF-α, IL-1, and IL-6, demonstrated excellent disease control. TNF-α antagonists (e.g., etanercept, adalimumab) are used to treat children with an inadequate response to methotrexate, with poor prognostic factors, or with severe disease onset. Early aggressive therapy with a combination of methotrexate and a TNF-α antagonist may result in earlier achievement of clinically inactive disease.

TNF inhibition is not as effective for the systemic symptoms found in sJIA. When systemic symptoms dominate systemic steroids are started followed by the initiation of IL-1 or IL-6 antagonist therapy, which often induces a dramatic and rapid response. Patients with severe disease activity may go directly to anakinra. Canakinumab, an IL-1β inhibitor, and tocilizumab, an IL-6 receptor antagonist, are

*Not indicated by the U.S. Food and Drug Administration for use in JIA.

bid, Twice daily; GI, gastrointestinal; IV, intravenous; PO, oral; SC, subcutaneous; tid, 3 times daily.
FDA-approved treatments for sJIA in children older than 2 yr. Standardized consensus treatment plans have been published to guide therapy for sJIA. These outline 4 treatment plans based on glucocorticoids, methotrexate, anakinra, or tocilizumab with optional glucocorticoid use in the latter 3 plans as clinically indicated.

With the advent of newer DMARDs, the use of systemic corticosteroids can often be avoided or minimized. Systemic steroids are recommended only for management of severe systemic illness, for bridge therapy during the wait for therapeutic response to a DMARD, and for control of uveitis. Steroids impose risks of severe toxicities, including Cushing syndrome, growth retardation, and osteopenia, and they do not prevent joint destruction.

Oral Janus kinase (JAK) inhibitors (tofacitinib, ruxolitinib) inhibit JAK signaling pathways involved in immune activation and inflammation. Tofacitinib is FDA approved for adults with rheumatoid arthritis.

Management of JIA must include periodic slit-lamp ophthalmologic examinations to monitor for asymptomatic uveitis (see Table 155-5; Figs. 155-15 and 155-16). Optimal treatment of uveitis requires collaboration between the ophthalmologist and rheumatologist. Initial management of uveitis may include mydriatics and corticosteroids used topically, systemically, or through periocular injection. DMARDs allow for a decrease in exposure to steroids, and methotrexate and antibodies to TNF-α (adalimumab and infliximab) are effective in treating severe uveitis.

Dietary evaluation and counseling to ensure appropriate calcium, vitamin D, protein, and caloric intake are important for children with JIA. Physical therapy and occupational therapy are invaluable adjuncts to any treatment program. A social worker and nurse clinician can be important resources for families, to recognize stresses imposed by a chronic illness, to identify appropriate community resources, and to aid compliance with the treatment protocol.

**PROGNOSIS**

Although the course of JIA in an individual child is unpredictable, some prognostic generalizations can be made on the basis of disease type and course. Studies analyzing management of JIA in the pre-TNF-α era indicate that up to 50% of patients with JIA have active disease persisting into early adulthood, often with severe limitations of physical function.

Children with persistent oligoarticular disease fare well, with a majority achieving disease remission. Those with extended oligoarticu-
Bibliography

Ankylosing Spondylitis and Other Spondyloarthritides

Pamela F. Weiss and Robert A. Colbert

The diseases collectively referred to as spondyloarthritides include ankylosing spondylitis (AS), arthritis associated with inflammatory bowel disease (IBD) and psoriasis, and reactive arthritis following gastrointestinal or genitourinary infections (Tables 156-1 and 156-2). Many children with spondyloarthritis are classified in the juvenile idiopathic arthritis (JIA) category of enthesitis-related arthritis (ERA). Children and adolescents with spondyloarthritis, who may not meet ERA criteria, include arthritis associated with psoriasis or IBD, juvenile AS (JAS), and reactive arthritis.

EPIEDEMOLOGY
JIA is diagnosed in 90 per 100,000 children in the United States every year (see Chapter 155). ERA accounts for 10-20% of JIA, and has a mean age of onset of 12 yr. Unlike other JIA categories, males are affected more often than females, accounting for 60% of ERA cases. AS occurs in 0.2-0.5% of adults, with approximately 15% of cases beginning in childhood. These disorders can be familial, largely as a result of the influence of HLA-B27, which is found in 90% of JAS and 50% of ERA compared to 7% of healthy individuals. Approximately 20% of children with ERA have a family history of HLA-B27–associated disease, such as reactive arthritis, AS, or IBD with sacroiliitis.

ETIOLOGY AND PATHOGENESIS
Spondyloarthritis are complex diseases in which susceptibility is largely genetically determined. HLA-B27 is responsible for 23.3% of AS heritability, with genes encoding the interleukin (IL)-23 receptor (IL23R), ERAP1 (endoplasmic reticulum aminopeptidase-1), IL-12p40 (IL12B), and others having important roles, but together accounting for only approximately 2% of heritability. Infection with certain gastrointestinal or genital pathogens can trigger reactive arthritis (see Chapter 157 and Table 156-2); environmental triggers for other forms of spondyloarthritis have not been identified. Unusual properties of HLA-B27, such as its tendency to misfold and form unusual cell surface structures, may have a role. Inflamed joints and entheses in spondyloarthritides contain T cells, B cells, macrophages, osteoclasts, proliferating fibroblasts and osteoblasts. Bone loss and osteoproliferation in and around vertebral bodies and facet joints in long-standing AS contribute to significant morbidity.

CLINICAL MANIFESTATIONS AND DIAGNOSIS
Clinical manifestations that help distinguish spondyloarthritides from other forms of juvenile arthritis include arthritis of the axial skeleton (sacroiliac joints) and hips, enthesitis (inflammation at the site of tendon, ligament, or joint capsule attachment to bone), symptomatic eye inflammation (acute anterior uveitis), and gastrointestinal inflammation (even in the absence of IBD) (see Table 156-1).

Enthesitis-Related Arthritis
Children have ERA if they have either arthritis and enthesitis or arthritis or enthesitis, with at least 2 of the following characteristics: (1) sacroiliac joint tenderness or inflammatory lumbosacral pain, (2) the presence of HLA-B27, (3) onset of arthritis in a male older than 6 yr,
Psoriatic Arthritis

Psoriatic arthritis accounts for approximately 10% of JIA. Common clinical features of psoriatic arthritis are nail pitting (Fig. 156-1), onycholysis, and dactylitis (sausage-like swelling of the fingers or toes).

Children have psoriatic arthritis if they have arthritis and psoriasis or arthritis and at least 2 of the following: (1) dactylitis, (2) nail pitting or onycholysis, or (3) psoriasis in a 1st-degree relative. The presence of psoriasis aids in diagnosis but is not required. Disease onset peaks during the preschool and early adolescent years. Children with onset during the preschool years are more often female, antinuclear antibody–positive, and at risk for asymptomatic ocular inflammation.

Disease onset during adolescence is equally common among males and females. In the majority of children, the arthritis is asymmetric and affects 4 or fewer joints at presentation. Large (knees and ankles) and small (fingers and toes) joints may be involved. Although distal interphalangeal joint involvement is uncommon, it is highly suggestive of the diagnosis. Enthesitis is detectable in 20-60% of patients and seems to be more frequent in those who present at an older age. Axial (sacroiliac) and root (hip) joints may be affected in up to 30% of children; the risk of axial arthritis is highest in those who are HLA-B27–positive.

Juvenile Ankylosing Spondylitis

JAS frequently begins with oligoarthritis and enthesitis. The arthritis occurs predominantly in the lower extremities and often involves the hips. In comparison to adult-onset AS, axial disease and inflammatory back pain are less frequent at disease onset, while enthesitis and peripheral arthritis are more common. AS is diagnosed according to the modified NY criteria if there is sufficient radiographic evidence of sacroiliitis (sacroiliitis of grade 2 or greater bilaterally or at least grade 3 unilaterally) and if the patient meets at least one clinical criterion involving inflammatory back pain, limitation of motion in the lumbar spine (Fig. 156-2), or limitation of chest expansion. JAS is present if the patient is <16 yr old. Juvenile onset AS is frequently used to describe adult AS when the symptoms began before 16 yr of age, but full criteria were not met until later.

To fulfill the modified New York criteria for AS, patients must have radiographic changes in the sacroiliac joints as well as clinical sequelae of axial disease. Because radiographic sacroiliitis can take many years to develop in adults and even longer in children, and clinical sequelae may lag further behind, criteria to identify pre-radiographic axial spondyloarthritis have been developed by the Assessment of SpondyloArthritis International Society. To meet criteria for axial spondyloarthritis patients must have at least 3 mo of back pain and sacroiliitis on imaging (acute inflammation on MRI or definite radiographic sacroiliitis by the New York criteria) plus 1 feature of spondyloarthritis (i.e., inflammatory back pain, arthritis, enthesitis [heel], uveitis, dactylitis, psoriasis, Crohn disease/ulcerative colitis, good response to nonsteroidal antiinflammatory drugs [NSAIDs], family history for spondyloarthritis, HLA-B27, or elevated C-reactive protein). Alternatively, patients can fulfill axial spondyloarthritis criteria if

Figure 156-1 Nail pitting (arrowhead) and “sausage digit” (dactylitis) of the left index finger of a girl with juvenile psoriatic arthritis. (From Petty RE, Malleson P: Spondyloarthropathies of childhood, Pediatr Clin North Am 33:1079–1096, 1986.)

Figure 156-2 Loss of lumbodorsal spine mobility in a boy with ankylosing spondylitis. The lower spine remains straight when the patient bends forward.
they are HLA-B27–positive and have at least 2 features of spondyloarthritis. These criteria have not been validated in the pediatric population but may be useful as a guide to evaluating preradiographic spondyloarthritis.

**Arthritis with Inflammatory Bowel Disease**
The presence of erythema nodosum, pyoderma gangrenosum, fever, weight loss, or anorexia in a child with chronic arthritis should raise suspicion of IBD. Two patterns of arthritis complicate IBD. Polyarthritis affecting large and small joints is most common and often reflects the activity of the intestinal inflammation. Less frequently, arthritis of the axial skeleton, including the sacroiliac joints, occurs, resulting in AS. As with psoriatic arthritis, the presence of HLA-B27 is a risk factor for the development of axial disease. The severity of axial involvement is independent of the activity of the gastrointestinal inflammation.

**LABORATORY FINDINGS**
Laboratory evidence of systemic inflammation with elevation of the erythrocyte sedimentation rate and/or C-reactive protein value is variable in most spondyloarthritides and may or may not be present at the onset of disease. Rheumatoid factor and antinuclear antibodies are absent, except in patients with psoriatic arthritis, of which as many as 50% are antinuclear antibody–positive. HLA-B27 is present in ~90% of children with JAS, compared with ~7% of healthy individuals but is less frequent in ERA and other types of spondyloarthritis.

**Imaging**
Conventional radiographs detect chronic bony changes and damage but not active inflammation. Early radiographic changes in the sacroiliac joints include indistinct margins and erosions that can result in joint space widening. Sclerosis typically starts on the iliac side of the joint (Fig. 156-3). Peripheral joints may exhibit periarticular osteoporosis, with loss of sharp cortical margins in areas of enthesis, which may eventually show erosions or bony spurs (enthesophytes). Squaring of the corners of the vertebral bodies and syndesmophyte formation resulting in the classic “bamboo spine” characteristic of advanced AS is rare in early disease, particularly in childhood. CT, like radiographs, can detect chronic bony changes but not active inflammation and has the disadvantage of more radiation exposure. The gold standard for early visualization of sacroiliitis is evidence of bone marrow edema adjacent to the joint on MRI with short T1 inversion recovery (STIR) sequences. Gadolinium does not add value to the study if STIR is used. MRI will reveal abnormalities before the plain radiograph. Whole body MRI is also used to evaluate the axial skeleton in adults with early disease as it can detect vertebral lesions in addition to sacroiliac changes.

**DIFFERENTIAL DIAGNOSIS**
The onset of arthritis following a recent history of diarrhea or symptoms of urethritis or conjunctivitis may suggest reactive arthritis (see Chapter 157). Lower back pain can be caused by suppurative arthritis of the sacroiliac joint, osteomyelitis of the pelvis or spine, osteoid osteoma of the posterior elements of the spine, pelvic muscle pyomyositis, or malignancies. In addition, mechanical conditions such as spondylolysis, spondylolisthesis, and Scheuermann disease should be considered. Back pain secondary to fibromyalgia usually affects the soft tissues of the upper back in a symmetric pattern and is associated with well-localized tender points and sleep disturbance (see Chapter 168.1). Legg-Calvé-Perthes disease (avascular necrosis of the femoral head), slipped capital femoral epiphysis, and chondrodysplasia may also manifest as pain over the inguinal ligament and loss of internal rotation of the hip joint, but without other features of spondyloarthropathies, such as involvement of other entheses and/or joints. Radiography or MRI is critical for distinguishing these conditions.

**TREATMENT**
The goals of therapy are to control inflammation, minimize pain, preserve function, and prevent ankylosis (fusion of adjacent bones) using a combination of antiinflammatory medications, physical therapy, and education. Treatment regimens for spondyloarthropathies include monotherapy or combination therapy with NSAIDs, disease-modifying antirheumatic drugs, or biologic agents. NSAIDs, such as naproxen (15–20 mg/kg/day), are frequently used initially and may reduce structural damage (syndesmophyte formation and growth) if used continuously. With relatively mild disease, intraarticular corticosteroids (e.g., triamcinolone hexacetonide) may also help to control peripheral joint inflammation. However, for moderate disease and JAS, it is typically necessary to add a second-line agent. Disease-modifying antirheumatic drugs such as sulfasalazine (up to 50 mg/kg/day; maximum 3 g/day) or methotrexate (10 mg/m²) may be beneficial for peripheral arthritis, but these medications have not been shown to improve axial disease in adults. Tumor necrosis factor-α inhibitors (e.g., etanercept, infliximab, adalimumab) have been efficacious in reducing symptoms and improving function in adults with AS, and there is evidence that similar responses are seen in children. It remains unclear whether tumor necrosis factor inhibitors have an impact on structural damage in established AS, underscoring the need for earlier recognition and better therapies.

Physical therapy and low-impact exercise should be included in the treatment program for all children with spondyloarthropathies. Exercise to maintain range of motion in the back, thorax, and affected joints should be instituted early in the disease course. Custom-fitted insoles are particularly useful in management of painful entheses around the feet, and the use of pillows to position the lower extremities while the child is in bed can be helpful.

**PROGNOSIS**
Observational studies suggest that ongoing disease activity for greater than 5 yr in juvenile spondyloarthropathies predicts disability. Disease remission occurs in less than 20% of children with spondyloarthropathies 5 yr after diagnosis. Factors associated with disease progression include tarsitis, HLA-B27 positivity, hip arthritis within the 1st 6 mo, and disease onset after age 8. Important questions, such as which patients with ERA will go on to have JAS/AS, have yet to be addressed. Outcomes for JAS compared with adult-onset AS suggest that hip disease requiring replacement is more common in children but axial disease is more severe in adults.

In addition to causing arthritis by means of direct microbial infection (i.e., septic arthritis; see Chapter 685), infection can lead to the generation and deposition of immune complexes as well as antibody or T cell–mediated cross-reactivity with self. Microbes may influence the immune response in ways that indirectly affect susceptibility to immune-mediated inflammatory diseases such as systemic lupus erythematosus, inflammatory bowel disease, juvenile idiopathic arthritis, and spondyloarthritis. Reactive and postinfectious arthritis are defined as joint inflammation caused by a sterile inflammatory reaction following a recent infection. We use reactive arthritis to refer to arthritis that occurs following enteropathic or urogenital infections and postinfectious arthritis to describe arthritis that occurs after infectious illnesses not classically considered in the reactive arthritis group, such as infection with group A streptococcus or viruses. In some cases, nonviable components of the initiating organism have been demonstrated in affected joints, and the presence of viable, yet nonculturable, bacteria within the joint remains an area of investigation.

The course of reactive arthritis is variable and may remit or progress to a chronic spondyloarthritis including ankylosing spondylitis (see Chapter 156). In postinfectious arthritis, the pain or joint swelling is usually transient, lasting less than 6 wk, and does not necessarily share the typical spondyloarthritis pattern of joint involvement. The distinction between postinfectious arthritis and reactive arthritis is not always clear, either clinically or in terms of pathophysiology.

**PATHOGENESIS**

Reactive arthritis typically follows enteric infection with *Salmonella* sp., *Shigella flexneri*, *Yersinia enterocolitica*, *Campylobacter jejuni*, or genitourinary tract infection with *Chlamydia trachomatis*. *Escherichia coli* and *Clostridium difficile* are also causative enteric agents, although less common (see Table 156-2 in Chapter 156). Although similar in some respects to reactive arthritis, acute rheumatic fever caused by group A streptococcus (see Chapters 183.1 and 438), arthritis associated with infective endocarditis (see Chapter 437), and the tenosynovitis associated with *Neisseria gonorrhoeae* are considered in later chapters.

Approximately 75% of patients with reactive arthritis are HLA-B27–positive. Incomplete elimination of bacteria and bacterial products, such as DNA, has been proposed as a factor in reactive arthritis. A relationship with clinical characteristics of specific infectious disorders is not present. In postinfectious arthritis, several viruses (rubella, varicella-zoster, herpes simplex, cytomegalovirus) have been isolated from the joints of patients. Antigens from other viruses (e.g., hepatitis B, adenovirus) have been identified in immune complexes from joint tissue.

Patients with reactive arthritis who are HLA-B27–positive have an increased frequency of acute and symptomatic uveitis and other extraarticular features. In addition, HLA-B27 is a risk factor for persistent gastrointestinal inflammation following enteric infections, even after resolution of the initial infection, and significantly increases the risk that the individual will develop chronic spondyloarthritis. Nevertheless, reactive arthritis also occurs in HLA-B27–negative patients, emphasizing the importance of other genes in disease susceptibility.

**CLINICAL MANIFESTATIONS AND DIFFERENTIAL DIAGNOSIS**

Symptoms of reactive arthritis begin approximately 2-4 wk following infection. The classic triad of arthritis, urethritis, and conjunctivitis is relatively uncommon in children. The arthritis is typically oligoarticular, with a predilection for lower extremities. Dactylitis may occur, and enthesitis (Fig. 157-1) is common (affects as many as 90% of patients; see Chapter 156). Cutaneous manifestations can occur and may include circinate balanitis, ulcerative vulvitis, oral lesions, erythema nodosum, and keratoderma blennorrhagica, which is similar in appearance to pustular psoriasis (Fig. 157-2). Systemic symptoms may include fever, malaise, and fatigue. Early in the disease course, markers of inflammation—erythrocyte sedimentation rate, C-reactive protein, and platelets—may be markedly elevated. The clinical manifestations may last for weeks to months.

Familiarity with other causes of postinfectious arthritis is vital when a diagnosis of reactive arthritis is being considered. Numerous viruses are associated with postinfectious arthritis (Table 157-1) and may result in particular patterns of joint involvement. Rubella and hepatitis B virus typically affect the small joints, whereas mumps and varicella often involve large joints, especially the knees. The hepatitis B arthritis–dermatitis syndrome is characterized by urticarial rash and a symmetric migratory polyarthritis resembling that of serum sickness. Rubella-associated arthropathy may follow natural rubella infection and, infrequently, rubella immunization. It typically occurs in young women, with an increased frequency with advancing age, and is uncommon in preadolescent children and in males. Arthralgia of the knees and hands usually begins within 7 days of onset of the rash or 10-28 days after immunization. Parvovirus B19, which is responsible
for erythema infectiosum (fifth disease), can cause arthralgia, symmetric joint swelling, and morning stiffness, particularly in adult women and less frequently in children. Arthritis occurs occasionally during cytomegalovirus infection and may occur during varicella infections but is rare after Epstein-Barr virus infection. Varicella may also be complicated by suppurative arthritis, usually secondary to group A streptococcal infection. HIV is associated with an arthritis that resembles psoriatic arthritis more than juvenile idiopathic arthritis (see Chapter 155).

Poststreptococcal arthritis is a postinfectious arthritis that may follow infection with either group A or group G streptococcus. It is typically oligoarticular, affecting lower extremity joints, and mild symptoms can persist for months. Poststreptococcal arthritis differs from rheumatic fever, which typically manifests with painful migratory polyarthritis of brief duration. Because valvular lesions have occasionally been documented by echocardiography after the acute illness, some clinicians consider poststreptococcal arthritis to be an incomplete form of acute rheumatic fever (see Chapter 183.1). Certain HLA-DRB1 types may predispose children to development of either poststreptococcal arthritis (HLA-DRB1*01) or acute rheumatic fever (HLA-DRB1*16).

Transient synovitis (toxic synovitis), another form of postinfectious arthritis, typically affects the hip, often after an upper respiratory tract infection (see Chapter 678.2). Boys from 3-10 yr of age are most commonly affected and have acute onset of severe pain in the hip (groin), with referred pain to the thigh or knee, lasting approximately 1 wk. The erythrocyte sedimentation rate and white blood cell count are usually normal. Radiologic or ultrasound examination may confirm widening of the joint space secondary to an effusion. Aspiration of joint fluid is often necessary to exclude septic arthritis and typically results in dramatic clinical improvement. The trigger is presumed to be viral, although responsible microbes have not been identified.

Nonsuppurative arthritis has been reported in children, usually adolescent boys, in association with severe truncal acne. Patients often have fever and persistent infection of the pustular lesions. Pyogenic (sterile) arthritis, pyoderma gangrenosum and acne (cystic) syndrome, an autosomal dominant disorder caused by a mutation in the PSTPIP1 gene, is a difficult-to-treat but rare autoinflammatory disorder that has responded to anakinra or anti–tumor necrosis factor antibody therapy in a few patients. Recurrent episodes of erosive arthritis begin in childhood, while cystic acne and the painful ulcerating lesions of pyoderma gangrenosum begin during adolescence. Recurrent episodes may also be associated with a sterile myopathy and may last for several months.

Infective endocarditis can be associated with arthralgia, arthritis, or signs suggestive of vasculitis, such as Osler nodes, Janeway lesions, and Roth spots. Postinfectious arthritis, perhaps because of immune complexes, also occurs in children with N. gonorrhoeae, Neisseria meningitidis, Haemophilus influenzae type b, and Mycoplasma pneumoniae infections.

**DIAGNOSIS**

A recent gentouriinary or gastrointestinal infection may suggest the diagnosis of reactive arthritis, but there is no diagnostic test. A complete blood count, acute phase reactants, complete metabolic panel, and urinalysis may be helpful to exclude other etiologies. Although stool or urogenital tract cultures can be performed in an attempt to isolate the triggering organism, the offending agent is not typically found at the time arthritis presents. Imaging findings are nonspecific or normal. Documenting previous streptococcal infection with antibody testing (anti-streptolysin O and anti-DNase B) may help to diagnose postinfectious arthritis. Serum sickness associated with the antibiotic treatment of preceding infection must be excluded.

Because the preceding infection can be remote or mild and often not recalled by the patient, it is also important to rule out other causes of arthritis. Acute and painful arthritis affecting a single joint suggests septic arthritis, mandating joint aspiration; osteomyelitis may cause pain and an effusion in an adjacent joint but is more often associated with focal bone pain and tenderness at the site of infection. Arthritis affecting a single joint, particularly the knee, may also be secondary to Lyme in endemic areas. The diagnosis of postinfectious arthritis is often established by exclusion, and after the arthritis has resolved. Arthritis associated with gastrointestinal symptoms or abnormal liver function test results may be triggered by infectious or autoimmune hepatitis. Arthritis or spondyloarthritis may occur in children with inflammatory bowel disease, such as Crohn disease or ulcerative colitis (see Chapter 336). When 2 or more blood cell lines are low or progressively decrease in a child with arthritis, parvovirus infection, macrophage activation (hemophagocytic) syndrome, and leukemia should be strongly considered. Persistent arthritis (>6 wk) suggests the possibility of a chronic rheumatic disease, including juvenile idiopathic arthritis (see Chapter 155 and 156) and systemic lupus erythematosus (see Chapter 158).

**TREATMENT**

Specific treatment is unnecessary for most cases of reactive or postinfectious arthritis. Nonsteroidal antiinflammatory agents are often needed for management of pain and functional limitation. Unless ongoing Chlamydial infection is suspected, attempts to treat the offending organism are not warranted. If swelling or arthralgia recurs, further evaluation may be necessary to exclude active infection or evolving rheumatic disease. Intraarticular steroid injections may be utilized for refractory or severely involved joints once acute infection has been ruled out. Systemic steroids or disease-modifying anti-rheumatic drugs are rarely indicated but may be considered for chronic disease. Participation in physical activity should be encouraged, and physical therapy may be needed to maintain normal function and prevent muscle atrophy. For postinfectious arthritis due to streptococcal disease, current recommendations include penicillin prophylaxis for at least 1 yr. Long-term prophylaxis is often recommended, but the duration is controversial and may need to be individualized.

**COMPLICATIONS AND PROGNOSIS**

Postinfectious arthritis following viral infections usually resolves without complications unless it is associated with involvement of other organs, such as encephalomyelitis. Children with reactive arthritis after enteric infections occasionally experience inflammatory bowel disease months to years after onset. Both uveitis and carditis have been reported in children diagnosed with reactive arthritis. Reactive arthritis, especially after bacterial enteric infection or genitourinary tract infection with C. trachomatis, has the potential for evolving to chronic arthritis, particularly spondyloarthritis (see Chapter 156). The presence of HLA-B27 or significant systemic features increases the risk of chronic disease.

**Table 157-1 Viruses Associated with Arthritis**

| TOGAVIRUSES | ADENOVIRUSES |

Bibliography
Systemic lupus erythematosus (SLE) is a chronic autoimmune disease characterized by multisystem inflammation and the presence of circulating autoantibodies directed against self-antigens. SLE occurs in both children and adults, disproportionately affecting females of reproductive age. Although nearly every organ may be affected, most commonly involved are the skin, joints, kidneys, blood-forming cells, blood vessels, and the central nervous system. Compared with adults, children and adolescents with SLE have more severe disease and more widespread organ involvement.

**ETIOLOGY**

The pathogenesis of SLE remains largely unelucidated, but several factors likely influence risk and severity of disease, including genetics, hormonal milieu, and environmental exposures.

A genetic predisposition to SLE is suggested by the association with specific genetic abnormalities, including congenital deficiencies of C1q, C2, and C4, as well as several polymorphisms (e.g., interferon regulatory factor 5 and protein tyrosine phosphatase N22), and familial clustering of SLE or other autoimmune disease. In addition, certain human leukocyte antigen (HLA) types (including HLA-B8, HLA-DR2, and HLA-DR3) occur with increased frequency in patients with SLE. Although SLE clearly has a genetic component, its occurrence is sporadic in families and its concordance is incomplete (estimated at 2-5% among dizygotic twins and 25-60% among monozygotic twins), suggesting that multiple genes are involved and that epigenetic and nongenetic factors are also important in disease expression.

Because SLE preferentially affects females, especially during their reproductive years, it is suspected that hormonal factors are important in pathogenesis. Of individuals with SLE, 90% are female, making gender the strongest risk factor for SLE. Estrogens are likely to play a role in SLE, and both in vitro and animal model studies suggest that estrogen exposure promotes B-cell autoreactivity. Estrogen-containing oral contraceptives do not appear to induce flares in quiescent SLE, although increased levels of apoptosis or significantly impaired ability to clear cell debris, causing prolonged exposure to nucleic antigens in the bloodstream and increased opportunity for recognition by immune cells, leading to B cell autoantibody production. Circulating autoantibodies form immune complexes and deposit in tissues, leading to local complement activation, initiation of a proinflammatory cascade, and, light exposure is known to aggravate SLE disease activity. Environmental influences also may induce epigenetic modifications to DNA, which increase the risk of SLE and drug-induced lupus; in mouse models, drugs such as procainamide and hydralazine can promote lymphocyte hypomethylation causing a lupus-like syndrome.

**EPIDEMIOLOGY**

The reported prevalence of SLE in children and adolescents (1-6/100,000) is lower than that in adults (20-70/100,000). Prevalence of SLE is highest among African-Americans, Asians, Hispanics, Native Americans, and Pacific Islanders for both adult and pediatric populations. SLE predominantly affects females, with reported 2-5:1 ratio prior to puberty, 9:1 ratio during reproductive years, and return to near prepubertal ratios in the postmenopausal period. Childhood SLE is rare before 5 yr of age and is usually diagnosed in adolescence, with a median age at diagnosis of 11-12 yr. Up to 20% of all individuals with SLE are diagnosed prior to age 16 yr.

**PATHOLOGY**

Histologic features most suggestive of SLE include findings in the kidney and skin, especially the discoid rash. Renal manifestations of SLE are classified histologically according to the criteria of the International Society of Nephrology (see Chapter 514). The finding of diffuse proliferative glomerulonephritis (class IV) significantly increases risk for renal morbidity. Renal biopsies are helpful to establish the diagnosis of SLE and to stage disease. Immune complexes are commonly found with “full house” deposition of immunoglobulin and complement. The characteristic discoid rash depicted in Figure 158-1D is characterized on biopsy by hyperkeratosis, follicular plugging, and infiltration of mononuclear cells into the dermal-epidermal junction. The histopathology of photosensitive rashes can be nonspecific, but immunofluorescence examination of both affected and nonaffected skin may reveal deposition of immune complexes within the dermal–epidermal junction. This finding is called the lupus band test, which is specific for SLE.

**PATHOGENESIS**

A hallmark of SLE is the generation of autoantibodies directed against self-antigens, particularly nucleic acids. These intracellular antigens are ubiquitously expressed but are usually inaccessible and cloistered within the cell. During cell necrosis or apoptosis, the antigens are released. SLE skin cells are highly susceptible to damage from ultraviolet light, and the resulting cell death leads to release of cell contents, including nucleic antigens. Individuals with SLE may have markedly increased levels of apoptosis or significantly impaired ability to clear cell debris, causing prolonged exposure to nucleic antigens in the bloodstream and increased opportunity for recognition by immune cells, leading to B cell autoantibody production. Circulating autoantibodies form immune complexes and deposit in tissues, leading to local complement activation, initiation of a proinflammatory cascade, and,

**Figure 158-1** Mucocutaneous manifestations of SLE. A, Malar rash; B, vasculitic rash on toes; C, oral mucosal ulcers; D, discoid rash in malar distribution.
ultimately, tissue damage. Antibodies to double-stranded DNA can form immune complexes, deposit in glomeruli, and initiate inflammation leading to glomerulonephritis. However, many individuals with SLE have circulating antibodies to double-stranded DNA yet do not have nephritis, suggesting that autoantibodies are not the only pathway leading to end organ damage in SLE.

Both the innate and adaptive arms of the immune system have been implicated in the dysregulation of the immune system seen in SLE. High levels of interferon-α production by plasmacytoid dendritic cells promote expression of other proinflammatory cytokines and chemokines, maturation of monocytes into myeloid dendritic cells, promotion of autoreactive B and T cells, and loss of self-tolerance. Many, but not all, patients with SLE exhibit this cytokine profile, known as the type 1 interferon signature. Other cytokines with increased expression in SLE include interleukin (IL)-1, IL-2, IL-6, IL-10, IL-12, IL-17, IL-21, interferon-γ, B-lymphocyte stimulator (BLYS), and anti–tumor necrosis factor-α.

Both B and T cells demonstrate functional impairments in SLE. In active SLE, B-cell populations have impaired tolerance and increased autoreactivity, enhancing B cells’ ability to produce autoantibodies following exposure to self-antigen. In addition, cytokines such as BLYS may promote abnormal B-cell number and function. T-cell abnormalities in SLE include increased numbers of memory T cells and decreased number and function of T-regulatory cells. SLE T cells display aberrant signaling and increased autoreactivity. As a result, they are resistant to attrition by normal apoptosis pathways.

**CLINICAL MANIFESTATIONS**

Any organ system can be involved in SLE, so the potential clinical manifestations are myriad (Table 158-1). The presentation of SLE in childhood or adolescence differs from that in adults. The most common presenting complaints of children with SLE include fever, fatigue, hematologic abnormalities, arthralgia, and arthritis. Arthritis is usually present in the 1st yr of diagnosis, may be asymptomatic (morning stiffness, painless swelling) but is often a symmetric polyarthritis affecting large and small joints. Tenosynovitis is often present, but radiologic joint changes are very rare. Pediatric lupus may develop in patients previously diagnosed with polyarticular or systemic juvenile idiopathic arthritis (see Chapter 155).

Renal disease in SLE is often asymptomatic, underscoring the need for careful monitoring of blood pressure and urinalyses; in adolescents, SLE often presents with nephrotic syndrome and/or renal failure with the predominant symptoms being edema, fatigue, changes in urine color, and nausea/vomiting. Because SLE symptoms and findings may develop serially over several years and not be present at one time, the diagnosis may require longitudinal follow up. SLE is often characterized by periods of flare and disease quiescence or may follow a more smoldering disease course. The neuropsychiatric complications of SLE may occur with or without apparently active SLE, posing a particularly difficult diagnostic challenge in adolescents, who are already at high risk for mood disorders (Fig. 158-2). Long-term complications of SLE and its therapy, including accelerated atherosclerosis and osteoporosis, become clinically evident in young to middle adulthood. SLE is a disease that evolves over time in each affected individual, and new manifestations may arise even many years after diagnosis.

**DIAGNOSIS**

The diagnosis of SLE requires a comprehensive clinical and laboratory assessment revealing characteristic multisystem disease and excluding other etiologies, including infection and malignancy. Presence of 4 of the 11 American College of Rheumatology (ACR) 1997 Revised Classification Criteria for SLE (Table 158-2) simultaneously or cumulatively over time establishes the diagnosis of SLE. Of note, although a positive antinuclear antibody (ANA) test result is not required for the diagnosis of SLE, ANA-negative lupus is extremely rare. Although ANA is very sensitive for SLE (95-99%), it is not very specific (~50%). Antibodies against double-stranded DNA and anti-Smith are specific for SLE (~98%) but not as sensitive (40-65%). Hypocomplementemia, although common in SLE, is not represented among the ACR classification criteria; hypocomplementemia has been added to updated criteria validated by the Systemic Lupus International Collaborating Clinics (SLICC) in 2012 (Table 158-3). Other differences in the SLICC criteria include addition of nonscarring alopecia, additional cutaneous and neurologic manifestations of lupus, and a positive direct Coombs test in the absence of hemolytic anemia.

**DIFFERENTIAL DIAGNOSIS**

Multorgan disease is the hallmark of SLE, and given its wide array of potential clinical manifestations, SLE is in the differential diagnosis of many clinical scenarios, including unexplained fevers, joint pain, arthritis, rash, cytopenias, neurologic or cardiopulmonary abnormalities, nephritis, and nephrotic syndrome. For patients ultimately diagnosed with pediatric SLE, the initial differential diagnosis often includes infections (sepsis, Epstein-Barr virus, parvovirus B19, endocarditis), malignancies (leukemia and lymphoma), poststreptococcal glomerulonephritis, other rheumatologic conditions (systemic onset juvenile idiopathic arthritis, vasculitides), and drug-induced lupus.

*Drug-induced lupus* refers to the presence of SLE manifestations triggered by exposure to specific medications, including minocycline, many anticonvulsants, sulphonamides, antiarrhythmic agents, and other drugs (Table 158-4). In individuals prone to SLE, these agents may act as a trigger for true SLE. In others, these agents provoke a reversible lupus-like syndrome. Unlike SLE, drug-induced lupus affects males and females equally. A genetic predisposition toward slow drug acetylation may increase the risk of drug-induced lupus. Circulating antihistone

*The presence of 4 of 11 criteria establishes the diagnosis of SLE. These criteria were developed for classification in clinical trials and not for clinical diagnosis. Each of these criteria counts as a single criterion whether 1 or more definitions are satisfied. Adapted from Hochberg MC: Updating the American College of Rheumatology revised criteria for the classification of systemic lupus erythematosus, Arthritis Rheum 40:1725, 1997.

Table 158-3  Systemic Lupus International Collaborating Clinics (SLICC) Classification Criteria for Systemic Lupus Erythematosus

**CLINICAL CRITERIA**
- Acute cutaneous lupus
  - Malar rash, bullous lupus, toxic epidermal necrolysis variant of SLE, maculopapular lupus rash, photosensitive lupus rash, or subacute cutaneous lupus
- Chronic cutaneous lupus
  - Classic discoid rash, lupus panniculitis, mucosal lupus, lupus erythematosus tumidus, chilblains lupus, discoid lupus/lichen planus overlap
- Oral or nasal ulcers
- Nonscarring alopecia
- Synovitis (≥2 joints)
- Serositis
  - Pleurisy or pericardial pain ≥1 day, pleural effusion or rub, pericardial effusion or rub, ECG evidence of pericarditis
- Renal
  - Presence of red blood cell casts or urine protein/creatinine ratio representing >500 mg protein/24 hours
- Neurologic
  - Seizures, psychosis, mononeuritis multiplex, myelitis, peripheral or cranial neuropathy, or acute confusional state
- Hemolytic anemia
  - Leukopenia (<4,000/mm³) or lymphopenia (<1,000/mm³)
  - Thrombocytopenia (<100,000/mm³)

**IMMUNOLOGIC CRITERIA**
- Positive antinuclear antibody
- Positive double-stranded DNA antibody
- Positive anti-Smith antibody
- Antiphospholipid antibody positivity
- Positive lupus anticoagulant, false-positive test for rapid plasma regain, medium to high titer antiphospholipid antibody level (IgA, IgG, IgM), or positive anti-β₂-glycoprotein I antibody (IgA, IgG, IgM)
- Low complement
  - Low C3, C4, or Ch50 level
- Positive direct Coombs test (in the absence of hemolytic anemia)

*The presence of 4 criteria (including at least 1 clinical and 1 immunologic criterion) establishes the diagnosis of SLE. Biopsy-proven lupus nephritis with positive ANA or anti–double-stranded DNA also satisfies the diagnosis of SLE. These criteria were developed for classification in clinical trials and not for clinical diagnosis. Adapted from Petri M: Derivation and validation of the Systemic Lupus International Collaborating Clinics classification criteria for systemic lupus erythematosus, Arthritis Rheum 64(8):2677–2686, 2012.
antibodies are often present in drug-induced SLE; these antibodies are only detected in up to 20% of individuals with SLE. Hepatitis, which is rare in SLE, is more common in drug-induced lupus. Individuals with drug-induced lupus are less likely to demonstrate antibodies to double-stranded DNA, hypocomplementemia, and significant renal or neurologic disease. In contrast to SLE, manifestations of drug-induced lupus typically resolve after withdrawal of the offending medication; however, complete recovery may take several months to years.

LABORATORY FINDINGS

A positive ANA test result is present in 95-99% of individuals with SLE. This test has poor specificity for SLE, as up to 20% of healthy individuals also have a positive ANA test result, making the ANA a poor screening test for SLE. ANA titers are not reflective of disease activity; therefore, repeating ANA titers is not helpful in disease management. Antibodies to double-stranded DNA are more specific for SLE, and in some individuals, anti–double-stranded DNA levels correlate with disease activity, particularly those with significant nephritis. Anti-Smith antibody, although found specifically in patients with SLE, does not correlate with disease activity. Serum levels of total hemolytic complement (CH50), C3, and C4 are typically decreased in active disease and often correlate with disease activity. Serum levels of total hemolytic complement (CH50), C3, and C4 are typically decreased in active disease and often improve with treatment; although hypocomplementemia is not included in the ACR classification criteria, it has been added to 2012 SLICC criteria, along with direct Coombs positivity. Table 158-5 lists autoantibodies found in SLE along with their clinical associations. Hypergammaglobulinemia is a common but nonspecific finding. Inflammatory markers, particularly erythrocyte sedimentation rate, are often elevated in active disease. C-reactive protein (CRP) correlates less well with disease activity and acutely elevated CRP values may reflect infection, while chronic mild elevation of CRP may indicate increased cardiovascular risk.

Antiphospholipid antibodies, which increase clotting risk, can be found in up to 66% of children and adolescents with SLE. Antiphospholipid antibodies can be detected by several means, and laboratory features that point to the presence of these antibodies include the presence of antiphospholipid antibodies, prolonged phospholipid-dependent coagulation test results (partial thromboplastin time, dilute Russell viper-venom time), and a circulating lupus anticoagulant (which confirms that a prolonged partial thromboplastin time is not corrected with mixing studies). When an arterial or venous clotting event occurs in the presence of an antiphospholipid antibody, antiphospholipid antibody syndrome is diagnosed. Antiphospholipid antibody syndrome can occur in the context of SLE or independent of SLE (see Chapter 479).

TREATMENT

Treatment of SLE is tailored to the individual and is based on specific disease manifestations and medication tolerability. For all patients, sunscreen and avoidance of prolonged direct sun exposure and other ultraviolet light may help control disease and should be reinforced at every visit with the patient. Hydroxychloroquine (5-7 mg/kg/day up to 400 mg/day) is recommended for all individuals with SLE if tolerated. In addition to treating mild SLE manifestations such as rash and mild arthritis, hydroxychloroquine prevents SLE flares, improves lipid profiles, and may have a beneficial impact on mortality and renal outcomes. Potential toxicities include retinal pigmentation and color vision impairment; therefore, ophthalmology exams every 6-12 mo are recommended for patients taking hydroxychloroquine. Nonsteroidal antiinflammatory agents can be useful for management of arthralgias and arthritis; it is important to keep in mind their potential hepatic, renal, and cardiovascular toxicities.

Corticosteroids are a mainstay for treatment of significant manifestations of SLE and work quickly to improve acute deterioration; side effects often limit patient compliance, especially in adolescence, and potential toxicities are worrisome. It is important to limit dose and length of exposure to corticosteroids whenever possible. Potential consequences of corticosteroid therapy include growth disturbance, weight gain, striae, acne, hyperglycemia, hypertension, cataracts, avascular necrosis, and osteoporosis. The optimal dosing of corticosteroids in children and adolescents with SLE remains unknown; severe disease is often treated with high doses of intravenous methylprednisolone (e.g., 30 mg/kg/day for 3 days, followed by weekly pulses) or high doses of oral prednisone (1-2 mg/kg/day). As disease manifestations improve, corticosteroid dosages are gradually tapered over months. It often becomes necessary to introduce steroid-sparing immunosuppressive medications in order to limit cumulative steroid exposure.

Steroid-sparing immunosuppressive agents often used in the treatment of pediatric SLE include methotrexate, leflunomide, azathioprine, mycophenolate mofetil, cyclophosphamide, and belimumab. Methotrexate, leflunomide, and azathioprine are often used to treat persistent moderate disease, including arthritis, significant cutaneous or hematologic involvement, and pleural disease. Intravenous or oral cyclophosphamide is reserved for the most severe, potentially life-threatening SLE manifestations, such as renal, neurologic, and cardiopulmonary disease. Although cyclophosphamide is highly effective in controlling disease, the potential toxicities are significant, including cytopenias, infection, hemorrhagic cystitis, premature gonadal failure, and increased risk of future malignancy. Attention to adequate hydration can attenuate the risk of hemorrhagic cystitis. Fortunately, young girls are at much lower risk of gonadal failure than older women, and the use of gonadotropin-releasing hormone agonists, such as leuprolide acetate, may help prevent gonadal failure. Clinical trial data on the
use of rituximab in SLE with treatment-resistant glomerulonephritis has been largely disappointing, but results from the LUNAR study suggest there may be benefit for subpopulations of SLE patients. The FDA has approved the use of belimumab (a monoclonal antibody against BlyS, also called B-cell activating factor); when added to standard SLE therapy, belimumab improves multiple markers of disease severity. BlyS levels are elevated in SLE and relate to disease activity. Treatment reduces the number of SLE flares and decreases the dose of prednisone. Side effects include fever, nausea, and diarrhea.

The Childhood Arthritis and Rheumatology Research Alliance has developed a consensus treatment plan induction therapy of newly-diagnosed proliferative lupus nephritis that is specific to the pediatric SLE population; these guidelines advise 6 mo of therapy with either cyclophosphamide or mycophenolate mofetil, used in combination with a standardized glucocorticoid regimen. For patients who fail to achieve a partial response in 6 mo it is appropriate to switch agents. Consensus statements for maintenance therapy of lupus nephritis recommend use of mycophenolate mofetil, every 3 mo IV cyclophosphamide or azathioprine for 12 mo after completing induction therapy.

Given the lifelong nature of SLE, optimal care of children and adolescents with this disease also involves preventive practices. Owing to the enhanced risk of atherosclerosis in SLE, attention to cholesterol levels, smoking status, body mass index, blood pressure, and other traditional cardiovascular risk factors is warranted. Even though the Atherosclerosis Prevention in Pediatric Lupus Erythematosus (APPLE) study failed to support placing all children with SLE on a statin, ad hoc analyses suggest that statins may be considered for primary prevention of atherosclerotic disease in certain clinical circumstances, particularly in pubertal patients with an elevated CRP. For all SLE patients, adequate intake of calcium and vitamin D is necessary to prevent future osteoporosis. Infections commonly complicate SLE, so routine immunization is recommended, as well as annual influenza vaccination and administration of the 23-valent pneumococcal vaccine. Prompt attention to febrile episodes should include an evaluation for serious infections. It should be remembered that pregnancy can worsen SLE, and obstetric complications are more common in SLE. In addition, many of the medications used to treat SLE are teratogenic. As a consequence, it is important to counsel adolescent girls about these risks and appropriate contraceptive options. SLE patients with antiphospholipid antibody syndrome are treated with long-term anticoagulation to prevent thrombotic events.

COMPLICATIONS

Within the 1st several yr of diagnosis, the most common causes of death in individuals with SLE include infection and complications of glomerulonephritis and neuropsychiatric disease (Table 158-6). Over the long-term, the most common causes of mortality also include complications of atherosclerosis and malignancy. The increased risk of premature atherosclerosis in SLE is not explained by traditional risk factors and is partly a result of the chronic immune dysregulation and inflammation associated with SLE. Increased malignancy rates may be caused by immune dysregulation as well as exposure to medications with carcinogenic potential.

PROGNOSIS

The severity of disease in pediatric SLE is notably worse than the typical course for most adult-onset SLE. However, owing to advances in the diagnosis and treatment of SLE, survival has improved dramatically over the past 50 yr. Currently, the 5 yr survival rate for pediatric SLE is ~95%, though the 10 yr survival rate remains ~80-90%. Given their long burden of disease, children and adolescents with SLE face a higher risk of future morbidity and mortality from the disease and its complications, especially atherosclerosis and malignancy (see Table 158-6). Given the complex and chronic nature of SLE, it is optimal for children and adolescents with SLE to be treated by pediatric rheumatologists in a multidisciplinary clinic.

Bibliography is available at Expert Consult.

158.1 Neonatal Lupus

Deborah Friedman, Rebecca E. Sadun, Stacy P. Ardoin, and Laura E. Schanberg

Neonatal lupus, an entity distinct from SLE, is one of the few rheumatic disorders manifesting in the neonate. Clinical manifestations of neonatal lupus include a characteristic annular or macular rash typically affecting the face (especially the periorbital area), trunk, and scalp (Fig. 158-3). The rash typically appears within the 1st 6 wk of life after exposure to ultraviolet light and lasts 3-4 mo; however, it can be present at birth. Infants may also have cytopenias and hepatitis, but the most feared complication is congenital heart block. Conduction system abnormalities range from prolongation of the PR interval to complete heart block, with development of progressive

![Figure 158-3 Neonatal lupus syndrome. Typical rash, often photosensitive with a malar distribution, appearing as annular plaques with erythema and scaling. Bibliography

Because maternal autoantibodies gain access to the fetus via the placenta at the 16th wk of gestation, all pregnant women with circulating anti-Ro or anti-La antibody (or those with a history of offspring with neonatal lupus or congenital heart block) are monitored by a pediatric cardiologist with regular fetal electrocardiography from 16 wk of gestation until delivery. If fetal bradycardia is found unexpectedly during in utero monitoring, screening for maternal anti-Ro and anti-La antibodies is warranted.

In contrast to SLE, neonatal lupus is not characterized by ongoing immune dysregulation, although infants with neonatal lupus may be at some increased risk for development of future autoimmune disease. A mother who has borne a child with congenital heart block caused by neonatal lupus has an approximately 17% risk of recurrence with future pregnancies. With cardiac pacing, children with conduction system disease in the absence of cardiomyopathy have an excellent prognosis. If the conduction defect is not addressed, affected children are at risk for exercise intolerance, arrhythmias, and death. A proposed management algorithm is presented in Figure 158-4.

Figure 158-4 Algorithm for the management of the anti-Ro ± anti-La pregnancy. All such pregnancies should include counseling and serial fetal echocardiograms.

Cardiomyopathy in the most severe cases. The noncardiac manifestations of neonatal lupus are usually reversible, whereas congenital heart block is permanent. Conduction system abnormalities can be detected in utero by fetal echocardiogram beginning at 16 wk of gestational age.

Neonatal lupus results from the passive transfer of maternal immunoglobulin G autoantibodies to the fetus. The vast majority of neonatal lupus cases are associated with maternal anti-Ro (also known as SSA) and anti-La antibodies (also known as SSB). Despite the clear association with maternal autoantibodies, their presence alone is not sufficient to cause disease, as ~2% of offspring born to mothers with anti-Ro and anti-La antibodies experience congenital heart block.

In vitro studies suggest that during cardiac development, Ro and La antigens may be exposed on the surface of cardiac cells in the proximity of the atrioventricular node, making the antigens accessible to maternal autoantibodies. Binding incites a local immune response, resulting in fibrosis within the conduction system as well as more extensive disease in fatal cases. In the skin, exposure to ultraviolet light results in cell damage and the subsequent exposure of Ro and La antigens, inducing a similar local inflammatory response that produces the characteristic rash.

Although the scant clinical trial data have been mixed, fluorinated corticosteroids (dexamethasone or betamethasone), intravenous immunoglobulin, plasmapheresis, hydroxychloroquine, and terbutaline (combined with steroids) have been used in pregnant women with anti-Ro or anti-La antibodies to prevent occurrence or progression of fetal cardiac abnormalities, including congenital heart block, endocardial fibroelastosis, and hydrops fetalis. Most encouraging are retrospective cohort studies suggesting maternal treatment with hydroxychloroquine may provide effective prophylaxis against congenital heart block. The mechanisms of action probably involve changes in acidification of endosomes and their interaction with Toll-like receptors. All clinical data on the use of hydroxychloroquine in pregnancy points to safety, and there are ongoing prospective clinical studies examining efficacy in the prevention of neonatal lupus syndrome in pregnant women known to be anti-Ro and/or anti-La positive.

Fluorinated corticosteroids seem to improve cases of hydrops. Significant conduction system abnormalities after birth are treated with cardiac pacing and occasionally intravenous immunoglobulin and steroids, while severe cardiomyopathy may require cardiac transplantation. Transient, noncardiac manifestations are conservatively managed, with topical steroids used occasionally to treat the rash.

Because maternal autoantibodies gain access to the fetus via the placenta at the 16th wk of gestation, all pregnant women with circulating anti-Ro or anti-La antibody (or those with a history of offspring with neonatal lupus or congenital heart block) are monitored by a pediatric cardiologist with regular fetal electrocardiography from 16 wk of gestation until delivery. If fetal bradycardia is found unexpectedly during in utero monitoring, screening for maternal anti-Ro and anti-La antibodies is warranted.

In contrast to SLE, neonatal lupus is not characterized by ongoing immune dysregulation, although infants with neonatal lupus may be at some increased risk for development of future autoimmune disease. A mother who has borne a child with congenital heart block caused by neonatal lupus has an approximately 17% risk of recurrence with future pregnancies. With cardiac pacing, children with conduction system disease in the absence of cardiomyopathy have an excellent prognosis. If the conduction defect is not addressed, affected children are at risk for exercise intolerance, arrhythmias, and death. A proposed management algorithm is presented in Figure 158-4.

Bibliography

Juvenile dermatomyositis (JDM) is the most common inflammatory myositis in children, distinguished by proximal muscle weakness and a characteristic rash. Inflammatory cell infiltrates result in vascular inflammation, the underlying pathology in this disorder.

**ETIOLOGY**

Evidence suggests that the etiology of JDM is multifactorial, based on genetic predisposition and an unknown environmental trigger. Human
leukocyte antigen (HLA) alleles such as B8, DRB1*0301, DQA1*0501, and DQA1*0501 are associated with increased susceptibility to JDM in selected populations. Maternal microchimerism may play a part in the etiology of JDM by causing graft-versus-host disease or autoimmune phenomena. Persistent maternal cells have been found in blood and tissue samples of children with JDM. An increased number of these maternal cells is positive for HLA-DQA1*0501, which may assist with transfer or persistence of chimeric cells. Specific cytokine polymorphisms in tumor necrosis factor-α promoter and variable number tandem repeats of the interleukin-1 receptor antagonist may increase genetic susceptibility. These polymorphisms are common in the general population. A history of infection in the 3 mo prior to disease onset is commonly reported; multiple studies have failed to produce a causative organism. Constitutional signs and upper respiratory symptoms predominate, but one-third of patients report preceding gastrointestinal (GI) symptoms. Group A streptococcus, upper respiratory infections, GI infections, coxsackievirus B, toxoplasma, enteroviruses, parvovirus B19, and multiple other organisms have been postulated as possible pathogens in the etiology of JDM. Despite these concerns, results of serum antibody testing and polymerase chain reaction amplification of the blood and muscle tissue for multiple infectious diseases have not been revealing. Environmental factors may also play a contributing role, with geographic and seasonal clustering reported; however, no clear theory of etiology has emerged.

**Epidemiology**

The incidence of JDM is approximately 3 cases/1 million children/yr without racial predilection. Peak age of onset is between 4 and 10 yr. There is a second peak of dermatomyositis onset in late adulthood (45-64 yr), but adult-onset dermatomyositis appears to be a distinctly separate entity in prognosis and etiology. In the United States, the ratio of girls to boys with JDM is 2:1. Multiple cases of myositis in a single family are rare, but familial autoimmune disease may be increased in families with children who have JDM than in families of healthy children. Reports of seasonal association have not been confirmed, although clusters of cases may occur.

**Pathogenesis**

Interferon upregulates genes critical in immunoregulation and major histocompatibility complex (MHC) class I expression, activates natural killer cells, and supports dendritic cell maturation. Upregulation of gene products controlled by type I interferons occurs in patients with dermatomyositis, potentially correlating with disease activity and holding promise as clinical biomarkers.

It appears that children with genetic susceptibility to JDM (HLA-DQA1*0501, HLA-DRB1*0301) may have prolonged exposure to maternal chimeric cells and/or an unknown environmental trigger. Once triggered, an inflammatory cascade with type I interferon response leads to upregulation of MHC class I expression and maturation of dendritic cells. Overexpression of MHC class I upregulates adhesion molecules, which influence migration of lymphocytes, leading to inflammatory infiltration of muscle. In an autoregulatory feedback loop, muscle inflammation increases the type I interferon response, regenerating the cycle of inflammation. Cells involved in the inflammatory cascade include natural killer cells (CD56), T-cell subsets (CD4, CD8, Th17), monocytes/macrophages (CD14), and plasmacytoid dendritic cells. Neopterin, interferon-inducible protein 10, monocytic chemotactic protein, myxovirus resistance protein, and von Willebrand factor products, as well as other markers of vascular inflammation may be elevated in patients with JDM who have active inflammation.

**Clinical Manifestations**

Children with JDM present with either rash, insidious onset of weakness, or both. Fears, dysphagia or dysphonia, arthritis, muscle tenderness, and fatigue are also commonly reported at diagnosis (Tables 159-1 and 159-2).

Rash develops as the first symptom in 50% of cases and appears concomitant with weakness only 25% of the time. Children often exhibit extreme photosensitivity to ultraviolet light exposure with generalized erythema in sun-exposed areas. If seen over the chest and neck, this erythema is known as the “shawl sign.” Erythema is also commonly seen over the knees and elbows. The characteristic heliotrope rash (Fig. 159-1) is a blue-violet discoloration of the eyelids that may be associated with periorbital edema. Facial erythema crossing the

Juvenile Dermatomyositis  1183

nasolabial folds is also common, in contrast to the malar rash without nasolabial involvement typical of systemic lupus erythematosus. Classic Gottron papules (Fig. 159-2) are bright pink or pale, shiny, thickened or atrophic plaques over the proximal interphalangeal joints and distal interphalangeal joints and occasionally on the knees, elbows, small joints of the toes, and ankle malleoli. The rash of JDM is sometimes mistaken for eczema or psoriasis. Rarely, a thickened erythematous and scaly rash develops in children over the palms (known as mechanic's hands) and soles along the flexor tendons, which is associated with anti-Jo-1 antibodies.

Evidence of small vessel inflammation is often visible in the nailfolds and gums as individual capillary loops that are thickened, tortuous, or absent (Fig. 159-3). Telangiectasias may be visible to the naked eye but are more easily visualized under capillaroscopy or with use of a magnifier such as an ophthalmoscope. Severe vascular inflammation causes cutaneous ulcers on toes, fingers, axillae, or epicantthal folds.

Weakness associated with JDM is often insidious and difficult to differentiate from fatigue at onset. It is typically symmetric, affecting proximal muscles such as the neck flexors, shoulder girdle, and hip flexors. Parents may report difficulty climbing stairs, combing hair, and getting out of bed. Examination reveals inability to perform a sit-up, head lag in a child after infancy, and Gower sign (use of hands on thighs to stand from a sitting position). Patients with JDM may roll to the side rather than sit straight up from lying to compensate for truncal weakness. Approximately half of children exhibit muscle tenderness as a result of muscle inflammation.

Esophageal and respiratory muscles are also affected, resulting in aspiration or respiratory failure. It is essential to assess for dysphonia or nasal speech, palatal elevation with gag, dysphagia, and gastroesophageal reflux by means of history, physical exam, and swallow study, if symptoms are present. Respiratory muscle weakness can be a medical emergency and lead to respiratory failure. Children with respiratory muscle weakness do not manifest typical symptoms of impending respiratory failure with increased work of breathing, instead demonstrating hypercarbia rather than hypoxemia.

Lipodystrophy and calcinosis (Fig. 159-4) are thought to be associated with long-standing or undertreated disease. Dystrophic deposition of calcium phosphate, hydroxyapatite, or fluoroapatite crystals occurs in subcutaneous plaques or nodules, resulting in painful ulceration of the skin with extrusion of crystals or calcific liquid. Calcinosis is reported in up to 40% of children with JDM, but the prevalence is thought to be lower in children who are treated early and aggressively. In rare instances, an “exoskeleton” of calcium deposition forms, greatly limiting mobility. Lipodystrophy results in progressive loss of subcutaneous and visceral fat, typically over the face and upper body, and may be associated with a metabolic syndrome similar to polycystic ovarian syndrome with insulin resistance, hirsutism, acanthosis,

Figure 159-1 The facial rash of juvenile dermatomyositis. There is erythema over the bridge of the nose and malar areas with violaceous (heliotropic) discolorations of the upper eyelids.

Figure 159-2 The rash of juvenile dermatomyositis. The skin over the metacarpal and proximal interphalangeal joints may be hypertrophic and pale red (Gottron papules).

B, The nailfold capillary pattern in a child with juvenile dermatomyositis shows dropout of capillary end loops, resulting in a wide band of avascularity. Dilated, tortuous capillaries can also be seen. C, Severe perungual telangiectasias may be seen without microscopy.
hypertriglyceridemia, and abnormal glucose tolerance. Lipodystrophy may be generalized or localized.

Rarely, vasculitis of the GI tract develops in children with severe JDM, with crampy abdominal pain, pancreatitis, GI bleeding, and potential for intestinal perforation or infarction. Involvement of the cardiac muscle with pericarditis, myocarditis, and conduction defects has been reported. An association with malignancy at disease onset is observed in adults with dermatomyositis but very rarely in children.

DIAGNOSIS
Diagnosis of dermatomyositis requires the presence of characteristic rash as well as at least three signs of muscle inflammation and weakness (see Table 159-1). Diagnostic criteria developed in 1975 predate the use of MRI and have not been validated in children. Diagnosis is often delayed because of the insidious nature of disease onset.

Electromyography shows signs of myopathy (increased insertional activity, fibrillations, and sharp waves) as well as muscle fiber necrosis (decreased action potential amplitude and duration). Nerve conduction studies are typically normal unless severe muscle necrosis and atrophy are present. It is important that electromyography (EMG) be performed in a center with experience in pediatric EMG and its interpretation. Muscle biopsy is typically indicated when diagnosis is in doubt or for grading disease severity. Biopsy of involved muscle reveals focal necrosis and phagocytosis of muscle fibers, fiber regeneration, endomysial proliferation, inflammatory cell infiltrates and vasculitis, and tubuloreticular inclusion bodies within endothelial cells. Findings of lymphoid structures and vasculopathy may portend more severe disease.

Some children present with classic rash but no apparent muscle weakness or inflammation; this variation is called amyoplastic JDM or dermatomyositis sine myositis. It is unclear whether these children have isolated skin disease or mild undetected muscle inflammation, risking progression to more severe muscle involvement with long-term sequelae such as calcinosis and lipodystrophy if untreated.

Differential diagnosis depends on the presenting symptoms. If the presenting complaint is solely weakness without rash or atypical disease, other causes of myopathy should be considered, including polymyositis, infection-related myositis (influenza A and B, coxsackievirus B, and other viral illnesses), muscular dystrophies (Duchenne and Becker as well as others), myasthenia gravis, Guillain-Barré syndrome, endocrinopathies (hyperthyroidism, hypothyroidism, Cushing syndrome, Addison disease, parathyroid disorders), mitochondrial myopathies, and metabolic disorders (glycogen and lipid storage diseases). Infections associated with prominent muscular symptoms include trichinosis, Bartonella infection, toxoplasmosis, and staphylococcal pyomyositis. Blunt trauma and crush injuries may lead to transient rhabdomyolysis with myoglobinuria. Myositis in children may also be associated with vaccinations, drugs, growth hormone, and graft-versus-host disease. The rash of JDM may be confused with eczema, dyschidrosis, psoriasis, malar rash from systemic lupus erythematosus, capillary telangiectasias from Raynaud phenomenon, and other rheumatic diseases. Muscle inflammation is also seen in children with systemic lupus erythematosus, juvenile idiopathic arthritis, mixed connective tissue disease, inflammatory bowel disease, and antineutrophil cytoplasmic antibody-positive vasculitides. Table 159-3 compares other juvenile inflammatory myositis disorders.

LABORATORY FINDINGS
Elevated serum levels of muscle-derived enzymes (creatine kinase, aldolase, aspartate aminotransferase, alanine aminotransferase, and lactate dehydrogenase) reflect muscle inflammation. Not all enzyme levels rise with inflammation in a specific individual; alanine aminotransferase is most commonly elevated on initial presentation, whereas the creatine kinase level may be normal. The erythrocyte sedimentation rate is often normal, and the rheumatoid factor test result is typically negative. There may be anemia consistent with chronic disease. Antinuclear antibody is present in >80% of children with JDM. Results of tests for antibodies to SSA, SSB, Sm, ribonucleoprotein, and double-stranded DNA are generally negative. Antibodies to Pm/ScI identify a small, distinct subgroup of myopathies with a protracted disease course, often complicated by pulmonary interstitial fibrosis and/or cardiac involvement. Similar to what is seen in adults, the presence of myositis-specific autoantibodies in JDM such as anti–Jo-1, anti–Mi-2, anti–p155/140, anti-NXP2, and other myositis-specific autoantibodies help define distinct clinical subsets and may predict the development of complications, although differences remain in certain aspects such as malignancy between adults and children.

Radiographic studies aid both diagnosis and medical management. MRI using T2-weighted images and fat suppression (Fig. 159-5) identifies active sites of disease, reducing sampling error and increasing the sensitivity of muscle biopsy and EMG, results of which are nondiagnostic in 20% of instances if the procedures are not directed by MRI. Extensive rash and abnormal MRI findings may be found despite normal serum levels of muscle-derived enzymes. Muscle biopsy often demonstrates evidence of disease activity and chronicity that is not suspected from the levels of the serum enzymes alone.

A contrast swallow study may document palatal dysfunction and risk of aspiration. Pulmonary function testing detects a restrictive defect consistent with respiratory weakness and reduced diffusion capacity of carbon monoxide from alveolar fibrosis associated with other connective tissue diseases. Serial measurement of vital capacity or negative inspiratory force can document changes in respiratory weakness, especially in an inpatient setting. Calcinosis is seen easily on radiographs, along the fascial planes and within muscles.
The aid of an experienced pediatric rheumatologist is invaluable in outlining an appropriate course of treatment for a child with JDM. Prior to the advent of corticosteroids, one-third of patients spontaneously improved, one-third had a chronic, lingering course, and one-third died from the disease. Corticosteroids have altered the course of disease, lowering morbidity and mortality. Methotrexate decreases the length of treatment with corticosteroids, thereby reducing morbidity from steroid toxicity. Intravenous gammaglobulin is frequently used as an adjunct for treatment of severe disease.

TREATMENT

The aid of an experienced pediatric rheumatologist is invaluable in outlining an appropriate course of treatment for a child with JDM. Prior to the advent of corticosteroids, one-third of patients spontaneously improved, one-third had a chronic, lingering course, and one-third died from the disease. Corticosteroids have altered the course of disease, lowering morbidity and mortality. Methotrexate decreases the length of treatment with corticosteroids, thereby reducing morbidity from steroid toxicity. Intravenous gammaglobulin is frequently used as an adjunct for treatment of severe disease.

Corticosteroids are still the mainstay of treatment. In a clinically stable child without debilitating weakness, oral prednisone at 2 mg/kg/day (maximum 60 mg daily) is usually started. Children with GI involvement have decreased absorption of oral steroids and require intravenous administration. In more-severe cases with respiratory or oropharyngeal weakness, high-dose pulse methylprednisolone is used (30 mg/kg/day for 3 days, maximum dose 1 g/day) with ongoing weekly or monthly IV dosing along with daily oral corticosteroids as needed. Corticosteroid dosage is slowly tapered over a period of 12 mo, after indicators of inflammation (muscle enzymes) normalize and strength improves.

Weekly oral, intravenous, or subcutaneous methotrexate (the lesser of 1 mg/kg or 15 mg/m², maximum 40 mg) is commonly used as a steroid-sparing agent in JDM. The concomitant use of methotrexate halves the cumulative dosage of steroids needed for disease control. Risks of methotrexate include immunosuppression, blood count dyscrasias, chemical hepatitis, pulmonary toxicity, nausea/vomiting, and teratogenicity. Folic acid is typically given with methotrexate starting at a dose of 1 mg daily to reduce toxicity and side effects of folate inhibition (oral ulcers, nausea, and anemia). Children who are taking immunosuppressive medications such as methotrexate should avoid live-virus vaccination, although inactivated influenza vaccination is recommended yearly.

Hydroxychloroquine has little toxicity risk and is used as a second- ary disease-modifying agent to reduce rash and maintain remission. Typically, it is administered at doses between 4 and 6 mg/kg/day orally.

* Removed from logistic regression analyses because variable was either 100% or 0% in 1 of the compared subgroups. Gottron papules and heliotrope rash, which were part of the definition of cases of dermatomyositis, were not entered into multivariable analyses.

not easily amenable to surgical intervention. Contrast-enhanced CT should be avoided if possible, because the GI vasculitis is diffuse and rest and aggressive treatment for the underlying inflammation. Surgery for emia, GI bleeding, and perforation if not treated with complete bowel rest. Rarely, children with severe involvement areas by MRI directs the location of the muscle biopsy or electromyography.

Figure 159-5 MRI using T2-weighting and fat suppression of the proximal muscle of the lower extremities of a child with juvenile dermatomyositis with normal muscle enzyme levels. There is focal inflammatory myopathy. The bright areas reflect the inflammatory response in involved muscle. The darker areas are more normal. Identification of involved areas by MRI directs the location of the muscle biopsy or electromyography.

in either tablet or liquid form. Ophthalmologic follow-up 1-2 times per year to monitor for rare retinal toxicity is recommended. Other side effects include hemolysis in patients with glucose-6-phosphate deficiency, GI intolerance, and skin/hair discoloration.

The use of rituximab in a trial of steroid-dependent patients with resistant inflammatory myopathies, including JDM, did not meet the primary study end point showing a difference in time to improvement between subjects given rituximab at baseline or at 8 wk, but overall, 83% of all subjects met the definition of improvement in the trial. Reports of the use of other biologic agents are based on case reports with mixed results.

Other medications for severe unresponsive disease include intravenous immunoglobulin, mycophenolate mofetil, cyclosporine, and cyclophosphamide. Children with pharyngeal weakness may need nasogastric or gastrostomy feedings to avoid aspiration, whereas those with GI vasculitis require full bowel rest. Rarely, children with severe respiratory weakness require ventilator therapy and even tracheostomy until the respiratory weakness improves.

Physical therapy and occupational therapy are integral parts of the treatment program, initially for passive stretching early in the disease course and then for direct reconditioning of muscles to regain strength and range of motion. Therapy may improve strength muscle measures and cardiovascular fitness. Bed rest is not indicated, because weight bearing improves bone density and prevents contractures. Social work and psychology services may facilitate adjustment to the frustration of physical impairment in a previously active child and aid with sleep disturbances associated with rheumatic disease.

All children with JDM should avoid sun exposure and apply high sun protection factor sunscreen daily, even in winter and on cloudy days. Vitamin D and calcium supplements are indicated for all children undergoing long-term corticosteroid therapy, in an attempt to reduce osteopenia and osteoporosis from medication.

**COMPLICATIONS**

Most complications from JDM are related to prolonged and severe weakness, including muscle atrophy, to cutaneous calcifications and scarring or atrophy, and to lipodystrophy. Secondary complications from medical treatments are also common. Children with acute and severe weakness are at risk for aspiration pneumonia and respiratory failure and occasionally require nasogastric feeding and mechanical ventilation until weakness improves. Crampy abdominal pain and occult GI bleeding may indicate bowel wall vasculitis and lead to ischemia, GI bleeding, and perforation if not treated with complete bowel rest and aggressive treatment for the underlying inflammation. Surgery should be avoided if possible, because the GI vasculitis is diffuse and not easily amenable to surgical intervention. Contrast-enhanced CT may show dilation or thickening of the bowel wall, intraluminal air, or evidence of bowel necrosis. Cardiac involvement by JDM is rare but includes arrhythmias.

Pathologic calcifications may be related to severity of disease and prolonged delay to treatment and potentially to genetic polymorphisms of tumor necrosis factor -α-308. Calcium deposits tend to form in subcutaneous tissue and along muscle. Some ulcerate through the skin and drain a soft calcific liquid, and others manifest as hard nodules along extensor surfaces or embedded along muscle. Draining lesions serve as a nidus for cellulitis or osteomyelitis. Nodules cause skin inflammation that may mimic cellulitis. Spontaneous regression of calcium deposits may occur, but there is no evidence-based recommendation for treatment of calcinosis.

Lipodystrophy manifests in 10-40% of patients with JDM and can be difficult to recognize. Fat atrophy may be generalized, partial, or local. Lipodystrophy has been associated with insulin resistance, acanthosis nigricans, dyslipidemia, hypertension, and menstrual irregularity, similar to features seen in polycystic ovarian disease or metabolic syndrome.

Children receiving prolonged corticosteroid therapy are prone to complications such as cessation of linear growth, weight gain, hirsutism, adrenal suppression, immunosuppression, striae, cushingoid fat deposition, mood changes, osteoporosis, cataracts, avascular necrosis, and steroid myopathy. Families should be counseled on the effects of corticosteroids and advised to use medical alert identification and to consult a nutritionist regarding a low-salt, low-fat diet with adequate vitamin D and calcium supplementation.

**PROGNOSIS**

The mortality rate in JDM has decreased since the advent of corticosteroids, from 33% to currently approximately 1%; little is known about the long-term consequences of persistent vascular inflammation. The period of active symptoms has decreased from about 3.5 yr to ≤1.5 yr with more aggressive immunosuppressive therapy; the vascular, skin, and muscle symptoms of children with JDM generally respond well to therapy. At 7 yr of follow-up, 75% of patients have little to no residual disability, but 25% continue to have chronic weakness and 40% have chronic rash. Up to one-third may need long-term medications to control their disease. Children with JDM appear able to repair inflammatory damage to vasculature and muscle.

Chapter 159  ❖  Juvenile Dermatomyositis  1186.e1

Bibliography
Juvenile scleroderma encompasses a range of conditions unified by the presence of fibrosis of the skin. Juvenile scleroderma is divided into 2 major categories, juvenile localized scleroderma (JLS, also known as morphea), which is largely limited to the skin, and juvenile systemic sclerosis (JSSc), with multisystem organ involvement. Localized disease is the predominant type seen in pediatric populations (>95%), but systemic sclerosis is associated with mortality and severe morbidity.
ETIOLOGY AND PATHOGENESIS
The etiology of scleroderma is unknown, but the mechanism of disease appears to be a combination of a vasculopathy, autoimmunity, immune activation, and fibrosis. Triggers, including trauma, infection, and, possibly, subclinical graft-versus-host reaction from persistent maternal cells (microchimerism), injure vascular endothelial cells, resulting in increased expression of adhesion molecules. These molecules entrap platelets and inflammatory cells, resulting in vascular changes with manifestations such as Raynaud phenomenon and pulmonary hypertension. Inflammatory cells infiltrate the area of initial vascular damage, causing further vascular damage and resulting in thickened artery walls and reduction in capillary numbers. Macrophages and other inflammatory cells then migrate into affected tissues and secrete cytokines that induce fibroblasts to reproduce and synthesize excessive amounts of collagen, resulting in fibrosis and subsequent lipodystrophy, dermal fibrosis, with loss of sweat glands and hair follicles. In late stages, the entire dermis may be replaced by compact collagen fibers.

Autoimmunity is believed to be a key process in the pathogenesis of both localized and systemic scleroderma, given the high percentage of affected children with autoantibodies. Children with localized disease often have a positive antinuclear antibody (ANA) test result (42%), and 47% of this subgroup have antithistone antibodies. Children with JSSc have higher rates of ANA positivity (80.7%) and may have anti-Scl 70 antibody (34%, antitopoisomerase I). The relationship between specific autoantibodies and the various forms of scleroderma is not well understood, and all antibody test results may be negative, especially in JLS.

CLASSIFICATION
Localized scleroderma is distinct from systemic scleroderma and rarely progresses to systemic disease. Within the category of JLS there are several subtypes that are differentiated by both the distribution of the lesions and the depth of involvement (Table 160-1). Up to 15% of children have a combination of 2 or more subtypes.

EPIDEMIOLOGY
Juvenile scleroderma is rare, with an estimated prevalence of 1/100,000. Localized scleroderma is far more common than SSc in children, by a 10:1 ratio, with limited scleroderma being the most common subtype. LS is predominantly a pediatric condition, with 65% of patients diagnosed before age 18 yr. After age 8 yr the female: male ratio for both LS and SSc is approximately 3:1, whereas in patients younger than 8 yr there is no sex predilection.

CLINICAL MANIFESTATIONS
Localized Scleroderma
The onset of scleroderma is generally insidious, and manifestations vary according to disease subtype. The initial skin manifestations of localized disease usually include erythema or a bluish hue seen around an area of waxy induration; subtle erythema may be the only presenting sign (Fig. 160-1). Edema and erythema are followed by indurated, hypopigmented or hyperpigmented, atrophic lesions (Fig. 160-2). LS varies in size from a few centimeters to the entire length of the extremity, with varying depth. Patients sometimes present with arthralgias, synovitis, or flexion contracts (Fig. 160-3). Children also experience limb length discrepancies as a result of growth impairment caused by involvement of muscle and bone. Children with en coup de sabre (Fig. 160-4) may have symptoms unique to central nervous system involvement, such as seizures, hemifacial atrophy, ipsilateral uveitis, and learning/behavioral changes.

Up to 25% of children with LS have extracutaneous manifestations, most commonly arthritis (47%) and neurologic symptoms (17%) associated with en coup de sabre.

Systemic Scleroderma
SSc also has an insidious onset with a prolonged course characterized by periods of remission and exacerbation, ending in either remission or, more commonly, chronic disability and death.

The skin manifestations of SSc include an early phase of edema that spreads proximally from the dorsum of the hands and fingers and includes the face. An eventual decrease in edema is followed by induration and fibrosis of skin, ultimately resulting in loss of subcutaneous fat, sweat glands, and hair follicles. Later, atrophic skin becomes shiny and waxy in appearance. As lesions spread proximally, flexion contracts develop at the elbows, hips, and knees associated with secondary muscle weakness and atrophy. In the face, this process results in a small oral type, with decreased mouth aperture. Skin ulceration over pressure points, such as the elbows, may be associated with subcutaneous calcifications. Severe Raynaud phenomenon causes ulceration of the fingertips with subsequent loss of tissue pulp and tapered fingers (sclerodactyly) (Fig. 160-5). Resorption of the distal tufts of the distal phalanges may occur (acroosteolysis). Hyperpigmented postinflammatory changes surrounded by atrophic depigmentation gives a

SYSTEMIC SCLEROSIS
Diffuse |
Most common type in childhood |
Symmetric thickening and hardening of the skin (sclerosis) with fibrous and degenerative changes of viscera |
Limited |
Rare in childhood |
Previously known as CREST (calcinosis cutis, Raynaud phenomenon, esophageal dysfunction, sclerodactyly, and telangiectasia) syndrome
salt-and-pepper appearance to skin. Over a period of years, remodeling of lesions sometimes results in focal improvement in skin thickening.

Pulmonary disease is the most common visceral manifestation of SSc and includes both arterial and interstitial involvement (alveolitis). Symptoms range from asymptomatic disease to exercise intolerance, dyspnea at rest, and right-sided heart failure. Pulmonary arterial hypertension is a poor prognostic sign, developing either as a consequence of lung disease or independently as part of the vasculopathy. Clinical manifestations of pulmonary arterial hypertension in children appear late in the course, are subtle, and include cough and dyspnea on exertion. Pulmonary evaluation should include pulmonary function testing, bronchoalveolar lavage, and high-resolution chest CT. Pulmonary function tests reveal decreased vital capacity and decreased diffusion of carbon monoxide capacity, while neutrophilia and/or eosinophilia on bronchoalveolar lavage suggest active alveolitis. Chest CT is much more sensitive than chest radiographs, which are often normal, showing typical basilar ground-glass abnormalities, reticular linear opacities, nodules, honeycombing, and mediastinal adenopathy.

Other organ systems include gastrointestinal tract disease, which is seen in 25% of children with the disease. Common manifestations include esophageal and intestinal dysmotility resulting in dysphagia, reflux, dyspepsia, gastroparesis, bacterial overgrowth, dilated bowel loops and pseudoobstruction, and dental caries, as well as malabsorption and failure to thrive. Renal arterial disease can cause chronic or severe episodic hypertension; unlike adult disease, renal crisis is rare. Cardiac fibrosis is associated with arrhythmias, ventricular hypertrophy, and decreased cardiac function. Mortality from JSSc is most commonly a result of cardiopulmonary disease.

**Raynaud Phenomenon**

Raynaud phenomenon (RP) is the most frequent initial symptom in pediatric systemic sclerosis, present in 70% of affected children months to years before other manifestations. RP refers to the classic triphasic sequence of blanching, cyanosis, and erythema of the digits induced
by cold exposure and/or emotional stress. RP is most commonly independent of an underlying rheumatic disease (Raynaud disease), but it can be a consequence of rheumatic diseases such as scleroderma, systemic lupus erythematosus, and mixed connective tissue disease (Table 160-2). The color changes are brought about by (1) initial arterial vasoconstriction, resulting in hypoperfusion and pallor (blanching), (2) venous stasis (cyanosis), and (3) reflex vasodilation caused by the factors released from the ischemic phase (erythema). The color change is classically reproduced by immersing the hands in iced water and reversed by warming. During the blanching phase, there is inadequate tissue perfusion in the affected area, associated with pain and paresthesias and resulting in ischemic damage only when associated with a rheumatic disease. The blanching usually affects the distal fingers, but may also involve thumbs, toes, ears, and tip of the nose. The affected area is usually well demarcated and uniformly white. Digital ulcers associated with RP are indicative of underlying rheumatic disease.

Raynaud disease often begins in adolescence and is characterized by symmetric occurrence, the absence of tissue necrosis and gangrene, and the lack of manifestations of an underlying rheumatic disease. Children have normal nail-fold capillaries (absence of periangual telangiectasias). RP should be distinguished from acrocyanosis and chilblains. Acrocyanosis is a vasospastic disorder resulting in cool, painless, bluish discoloration in the hands and sometimes feet despite normal tissue perfusion. It may be exacerbated by stimulant medications used to treat attention deficit disorder. Chilblains is a condition with episodic color changes and the development of nodules related to severe cold exposure and spasm-induced vessel and tissue damage; this condition has been associated with systemic lupus erythematosus.

**DIAGNOSIS**

The diagnosis of localized scleroderma is based on the distribution and depth of characteristic lesions. Biopsy is helpful to confirm the diagnosis. The diagnosis of JSSc requires proximal sclerosis/induration of the skin as well as the presence of 2 of 20 minor criteria (Table 160-3).

**DIFFERENTIAL DIAGNOSIS**

The most important condition to differentiate from JLS is JSSc. Contractions and synovitis from juvenile arthritis can be differentiated from those due to linear scleroderma by the absence of skin changes. Other conditions to consider include chemically induced scleroderma-like disease, diabetic cheiroarthritis, pseudoscleroderma, and scleredema. Pseudoscleroderma is composed of a group of unrelated diseases characterized by patchy or diffuse cutaneous fibrosis without the other manifestations of scleroderma. These include phenylketonuria, syndromes of premature aging, and localized idiopathic fibrosis. Scleredema is a transient, self-limited disease of both children and adults that has sudden onset after a febrile illness (especially streptococcal infections) and is characterized by patchy sclerodermatous lesions on the neck and shoulders and extending to the face, trunk, and arms.

**LABORATORY FINDINGS**

There are no laboratory studies diagnostic of either localized or systemic scleroderma. Although the results of complete blood counts, serum chemistry analyses, and urinalysis are normal, children may have elevated erythrocyte sedimentation rate, eosinophilia, or hypergammaglobulinemia, all of which normalize with treatment. Elevations of muscle enzymes, particularly aldolase, can be seen with muscle involvement. Patients with JSSc may have anemia, leukocytosis, and eosinophilia and autoantibodies (ANA, anti-Scl 70). Imaging studies delineate the affected area and can be used to follow disease progression. MRI is useful in en coup de sabre and Parry Romberg syndrome for determination of central nervous system or orbital involvement. Infrared thermography utilizes the temperature variation between areas of active and inactive cutaneous disease to help differentiate active disease from damage. The role of ultrasound to look at lesion activity is evolving. High-resolution CT, pulmonary function tests, echocardiography, and manometry are useful tools for diagnosing and monitoring visceral involvement in JSSc.
TREATMENT

Treatment for scleroderma varies according to the subtype and severity. Superficial morphea may benefit from topical corticosteroids or ultraviolet therapy. For lesions involving deeper structures, systemic therapy is recommended. A combination of methotrexate and corticosteroids is effective in treating JLS by preventing lesion extension and resulting in significant skin softening and improved range of motion of affected joints. The treatment plan for JLS includes: (1) weekly subcutaneous methotrexate given at 1/mg/kg weekly (maximum dose: 25 mg); (2) weekly methotrexate as in (1) plus either 3 mo of high-dose intravenous corticosteroids (30 mg/kg, maximum dose: 1,000 mg) for 3 consecutive days a month or weekly corticosteroids at the same dose for 3 mo; (3) high daily oral corticosteroids (2 mg/kg/day, maximum: 60 mg) with a slow taper over 48 wk. Mycophenolate mofetil is a second-line agent for recalcitrant disease. Physical and occupational therapy are important adjuncts to pharmacologic treatment. Eosinophilic fasciitis often responds well to corticosteroids and methotrexate.

Treatments for JSSc target specific disease manifestations. RP is treated with cold avoidance with pharmacologic interventions are reserved for severe disease. Calcium channel blockers (nifedipine 30-60 mg of sustained-release form daily, amlodipine 2.5-10 mg daily) are the most common pharmacologic interventions. Additional potential therapies for RP include losartan, prazosin, bosentan, and sildenafil. Angiotensin-converting enzyme inhibitors (captopril, enalapril) are recommended for hypertension associated with renal disease. Methotrexate or mycophenolate mofetil may be beneficial for skin manifestations. Cyclophosphamide and mycophenolate mofetil are used to treat pulmonary alveolitis and prevent fibrosis. Corticosteroids should be used cautiously in systemic sclerosis because of an association with renal crisis. Adults with systemic sclerosis have been successfully treated with high-dose cyclophosphamide, antithymocyte globulin and autologous stem cell transplantation.

The treatment of RP begins with avoiding cold stimuli, use of hand and foot warmers, and avoiding carrying bags by their handles (impairs circulation). Nifedipine (10-20 mg tid adult dose) reduces but does not eliminate the number and severity of episodes. Side effects include headache, flushing, and hypotension. Topical nitrates may result in digital vasodilation and may reduce the severity of an episode.

PROGNOSIS

Localized scleroderma is generally self-limited, with initial inflammatory stage followed by a period of stabilization and then softening for an average disease duration of 3-5 yr; however there are reports of active disease lasting up to 20 yr. Prolonged disease activity is associated primarily with linear and deep disease subtypes. Localized scleroderma, especially linear and deep subtypes, can result in significant morbidity, disfigurement, and disability as a result of joint contractures, muscle atrophy, limb shortening, facial asymmetry, and hyper- and hypopigmentation. Death from a en coup de sabre lesion with progressive neurologic decline has been reported.

JSSc has a more variable prognosis. Although many children have a slow, insidious course, others demonstrate a rapidly progressive form with early organ failure and death. Skin manifestations reportedly soften years after disease onset. Overall, the prognosis of JSSc is better than that of the adult form, with 5-, 10-, and 15-year survival rates, respectively, in children of 89%, 80-87%, and 74-87%. The most common cause of death is heart failure caused by myocardial and pulmonary fibrosis.

Bibliography is available at Expert Consult.
Bibliography

Behçet disease (BD) is classified as a primary variable vessel vasculitis, emphasizing the involvement of any size and type (arterial, venous) of vessel. BD is also recognized as an autoinflammatory disease. Originally described with recurrent oral ulcerations, uveitis and skin abnormalities, the spectrum is much broader.

**EPIDEMIOLOGY**
BD has a high prevalence in countries along the Silk Road, extending from Japan to the eastern Mediterranean. It is increasingly recognized among people of European ancestry. BD has a prevalence of 5-7 per 100,000 adults, which makes it more frequent than the other vasculitides such as granulomatosis polyangiitis (Wegener disease). The increased disease recognition might have had a role in the rising prevalences as well as the immigrations of the 20th century. Prevalence in children is probably not more than 10% of the adult counterparts in eastern Mediterranean countries. In children, boys and girls are equally affected. Family history of BD is present in approximately 20% of the cases. Onset in children is 8-12 yr of age; newborns of affected mothers have demonstrated symptoms of BD.

**ETIOLOGY AND PATHOGENESIS**
BD is a polygenic autoinflammatory disorder. Genetic contribution to BD is evident through the well-known association with HLA-B5101, the familial cases, the sibling and twin recurrence rate, the specific frequency of the disease among people along the Silk Road, evidence for genetic anticipation and the genome wide analysis studies that support the genetic contribution in the pathogenesis. Genome wide analysis studies among Turkish and Japanese BD patients confirm the marked association with HLA-B5101. Other significant associations include interleukin (IL)-10 and IL-23R/IL-12RB2 genes. Other possible susceptibility loci in a Turkish cohort demonstrate associations in STAT4 (a transcription factor in a signaling pathway related to cytokines such as IL-12, type I interferons, and IL-23), and ERAP1 (an endoplasmic reticulum–expressed aminopeptidase that functions in processing of peptides onto major histocompatibility complex class I).

The autoinflammatory nature of the disease is suggested by the episodic nature of the disease, the prominent innate immune system activation, the absence of identifiable autoantibodies and the co-association with the MEFV (Mediterranean fever) gene. An infectious agent may be responsible for inducing the aberrant innate immune system attacks in the genetically predisposed host. A number of infectious agents have been implicated and include streptococci, herpes simplex virus type 1, and parvovirus B19.

**CLINICAL MANIFESTATIONS AND DIAGNOSIS**
The course of BD is characterized by exacerbations and remissions. There is also marked heterogeneity in disease manifestation (Table 161-1).

The mean age of the first symptom is between 8 and 12 yr. The most frequent initial symptom is a painful oral ulcer (Fig. 161-1). The oral ulcers are often recurrent, may be single or multiple, range from 2-10 mm, and may be in any location in the oral cavity. They are often very painful. The oral ulcers last 3-10 days and heal without scarring. In contrast, the genital ulcers heal with scars. Genital scars are noted in 60% of the patients, usually occur after puberty, and are seen on the labia, scrotum, penis, or the anal area.

Another key feature of BD that has significant morbidity is bilateral eye involvement seen in 30-60% of pediatric patients. The main symptoms of anterior uveitis are blurred vision, redness, periorbital or
global pain, and photophobia. Although it is often in the form of panuveitis, anterior uveitis may be seen in females. Uveitis in general is more common in males. Vitreitis and retinal vasculitis are the most prominent features of posterior involvement. Complications of uveitis include blindness (unusual with treatment), glaucoma, and cataracts. Retinal vasculitis, retinal detachment, and retrobulbar neuritis (optic neuritis) are less-common eye manifestations of BD.

The skin lesions of BD range from erythema nodosum, papulopustular acneiform lesions, folliculitis, purpura, and ulcers. Pathergy is also a skin feature that is a pustular reaction occurring 24-48 hr after a sterile needle puncture or saline injection; it is not pathognomonic of BD.

The vasculitis of BD involves both arterial or venous thrombosis and aneurysm formation or occlusions or stenosis in arteries of any size. In children deep venous thrombosis of the lower limbs is the most frequent vasculitic feature. If the hepatic vein is thrombosed Budd-Chiari syndrome may occur. Pulmonary aneurysms are the most severe feature of pediatric BD, associated with the highest mortality. Coronary artery aneurysms may confuse BD with Kawasaki disease. Microvascular involvement may be noted in the nail bed capillaries.

Central nervous system (CNS) manifestations in children include meningoencephalitis (headache, meningismus, cerebrospinal fluid pleocytosis), encephalomyelitis, pseudotumor cerebri, dural sinus thrombosis, and organic psychiatric disorders (psychosis, depression, dementia). Dural sinus thrombosis is the most common CNS manifestation in children.

Gastrointestinal involvement manifests with abdominal pain, diarrhea, and intestinal ulcerations, most often in the ileocecal region. Gastrointestinal BD may be difficult to distinguish from inflammatory bowel disease. Oligoarticular arthritis/arthralgia is present in more than 50% of the patients and can be recurrent, but is nondeforming. Other rare manifestations include orchitis, renal vasculitis, glomerulonephritis, or amyloidosis and cardiac involvement.

### DIAGNOSIS

The International Study Group criteria are most widely used and require the presence of oral ulcers (at least 3 times per year) along with 2 other major features, including genital ulcers, a positive pathergy test, uveitis, and the characteristic skin lesions (see Table 161-1). If only 1 of the criteria is present along with oral ulcerations, the term incomplete or partial Behçet disease is applied. There are no specific laboratory tests. Acute-phase reactants are often mildly elevated. The diagnosis relies on the constellation of symptoms and excluding other causes.

### TREATMENT AND PROGNOSIS

Azathioprine is highly recommended to treat inflammatory eye disease. For oral and genital ulcers topical treatment is recommended (sucralfate, steroids). Colchicine is recommended for erythema nodosum or arthritis in males and females and for genital ulcers in females. There is no evidence-based treatment for gastrointestinal disease, but thalidomide, sulfasalazine, steroids, azathioprine and anti-tumor necrosis factor (TNF) agents have been recommended. For CNS disease and vasculitis, steroids, azathioprine, cyclophosphamide, interferon alpha, and in unresponsive CNS disease anti-TNF agents are suggested. There is no consensus about the benefit of anticoagulation in the management of vein thrombosis in BD.

In patients without major organ involvement, colchicine significantly improves oral and genital ulcers, skin features, and disease activity. In pediatric patients with vascular involvement with venous thrombosis, steroids and azathioprine have been used, whereas those with pulmonary arterial or cardiac involvement are initially treated with cyclophosphamide; follow-up of at least 18 mo demonstrated that those treated are free of vascular relapses. Patients treated with anti-TNF drugs have had persistent responses in 90%, 89%, 100%, and 91% of patients with resistant mucocutaneous, ocular, gastrointestinal, and central nervous system involvement, respectively.

Mortality in children with BD is low except for the pulmonary aneurysms. However, BD is a chronic disease associated with significant morbidity. Early diagnosis and effective treatment improves the outcome of BD.

**Figure 161-1 Oral aphthous lesion in a girl with Behçet disease.**

(From Ozen S, Petty RE: Behçet disease. In Cassidy JT, Petty RE, Laxer RM, et al, editors, Textbook of pediatric rheumatology, ed 6, Philadelphia, 2011, Saunders, Fig. 36-1, p. 554.)
Bibliography

Sjögren syndrome is a chronic, inflammatory, autoimmune disease characterized by progressive lymphocytic and plasma cell infiltration of the exocrine glands, especially salivary and lacrimal, with potential for systemic manifestations. It is rare in children and predominantly affects middle-age women with classic symptoms of dry eyes (keratoconjunctivitis sicca) and dry mouth (xerostomia).

**EPIDEMIOLOGY**

Sjögren syndrome typically manifests at 35-45 yr of age, with 90% of cases among women, but it is underrecognized in children as symptoms often start in childhood. The mean age at diagnosis in children is 9-10 yr; 75% are girls. The disease can occur as an isolated disorder, referred to as primary Sjögren syndrome (sicca complex), or as a secondary Sjögren syndrome in association with other rheumatic disorders such as systemic lupus erythematosus, scleroderma, or mixed connective tissue disease, and usually precedes the associated autoimmune disease by years.

**ETIOLOGY AND PATHOGENESIS**

The etiology of Sjögren syndrome is complex and includes genetic predisposition and possibly an infectious trigger. Lymphocytes and plasma cells infiltrate salivary glands, forming distinct periductal and pericellular foci that become confluent and may replace epithelial structure. Several genes regulating apoptosis influence the chronicity of lymphocytic infiltration.

**CLINICAL MANIFESTATIONS**

International classification criteria have been developed for the diagnosis of Sjögren syndrome in adult patients, but these criteria apply poorly to children. Although diagnostic criteria in children have been proposed, they have not been validated (Table 162-1). Recurrent parotid gland enlargement and parotitis are the most common manifestations in children (>70%), whereas sicca syndrome (dry mouth, painful mucosa, sensitivity to spicy foods, halitosis, widespread dental caries) predominate in adults. In a cross sectional study of children with Sjögren syndrome, manifestations included recurrent parotitis (72%), sicca symptoms (38%), polyarthritis (18%), vulvovaginitis (12%), hepatitis (10%), Raynaud phenomenon (10%), fever (8%), renal tubular acidosis (9%), lymphadenopathy (8%), and central nervous system involvement (5%).

Subjective symptoms of xerostomia complaints are relatively rare in juvenile cases, perhaps indicating that Sjögren syndrome is a slowly progressive disease; however increased dental caries is seen clinically in children. Serologic markers (antinuclear antibodies, and antibodies to Ro [SSA] and SS B [La]) and articular manifestations are significantly more frequent in adults. Frequencies of the finding of antinuclear antibodies and SSA and SSB antibodies in children are reported to be 78%, 75%, and 65%, respectively, with rheumatoid factor present in 67%. Additional clinical manifestations from a variety of organ involvement patterns include a decreased sense of smell, hoarseness, chronic otitis media, leukocytoclastic vasculitis (purpura), and internal organ exocrine disease involving the lungs (diffuse interstitial lymphocytosis), pancreas, hepatobiliary system, gastrointestinal tract, kidneys (renal tubular acidosis), musculoskeletal (arthritis and arthralgia), hematologic (cytopenias), peripheral nervous system (sensory and autonomic neuropathy), and central nervous system (optic neuritis, transverse myelitis, meningoencephalitis).

**DIAGNOSIS**

Clinical presentation of recurrent parotitis and/or recurrent parotid gland swelling in a child or adolescent is characteristic and should raise the suspicion for this disorder. The diagnosis is based on clinical features supported by biopsy of salivary or parotid glands demonstrating foci of lymphocytic infiltration, the current gold standard for diagnosis. Children are more likely to have normal minor salivary gland but abnormal parotid gland biopsies. Supporting laboratory abnormalities include cryoglobulinemia, elevated erythrocyte sedimentation rate, hypergammaglobulinemia, positive rheumatoid factor, and detection of SSA and SS B antibodies. Anti-β-fodrin autoantibodies, directed against an apoptotic cleavage product of α-fodrin, are a useful diagnostic marker for juvenile Sjögren syndrome. The Schirmer test detects abnormal tear production (≤ 5 mm of wetting of filter paper strip in 5 min) and Rose-Bengal staining detects damaged ocular epithelial conjunctival and corneal cells. Imaging studies, including MRI, technetium 99mTc scintigraphy, and sialography, are useful in the diagnostic evaluation for Sjögren syndrome (Fig. 162-1).

**DIFFERENTIAL DIAGNOSIS**

The differential diagnosis of Sjögren syndrome in children includes juvenile recurrent parotitis, characterized by intermittent unilateral parotid swelling typically lasting only a few days. It is frequently associated with fever and may undergo remission with puberty. Unlike in Sjögren syndrome, there is a male predominance, it is seen in the younger children (3-6 yr of age), and there is a lack of focal lymphocytic infiltrates on biopsy. Other conditions in the differential diagnosis include eating disorders, infectious parotitis (mumps, streptococcal and staphylococcal infections, Epstein-Barr virus, cytomegalovirus, HIV, parainfluenza, influenza enterovirus) and local trauma to the buccal mucosa. Rarely, polycystic parotid disease, tumors, and sarcoidosis may present with recurrent parotid swelling. In these conditions, non-exocrine disease manifestations of Sjögren syndrome may be related to inflammatory vascular disease (in skin, muscle and joints, serosal surfaces, and peripheral and central nervous systems), noninflammatory vascular disease (Raynaud phenomenon), mediator-induced disease (hematologic cytopenias, fatigue, and fever), and autoimmune endocrinopathy (thyroiditis).

| 7. Positive findings of parotid gland scintigraphy |

| IV. Exclusion of all other autoimmune diseases |

Diagnosis requires 4 criteria.

sicca complex, rash, arthralgia, and antinuclear antibodies are usually absent.

**TREATMENT**
Symptomatic treatment of Sjögren syndrome includes the use of artificial tears, massage of the parotids, oral lozenges, and fluids to limit the damaging effects of decreased secretions. Corticosteroids, nonsteroidal antiinflammatory drugs, and hydroxychloroquine are among the more commonly used agents for treatment, with reports of methotrexate and etanercept used for treatment of arthritis. Stronger immunosuppressive agents, such as cyclosporine and cyclophosphamide, are reserved for severe functional disorders and life-threatening complications.

**COMPLICATIONS AND PROGNOSIS**
The symptoms of Sjögren syndrome develop and progress slowly. Diminished salivary flow typically remains constant for years. Because monoclonal B-lymphocyte disease originates chiefly from lymphocytic foci within salivary glands or from parenchymal internal organs, there is increased risk for mucosa-associated lymphoid tissue lymphoma. Maternal Sjögren syndrome can be an antecedent to the neonatal lupus syndrome (see Chapter 158.1).

Bibliography
The hereditary periodic fever syndromes are a group of monogenic diseases that present with recurrent bouts of fever and associated pleural and/or peritoneal inflammation, arthritis, and various types of skin rash. They are subsumed among a larger group of disorders, the systemic autoinflammatory diseases, that were first recognized for their seemingly unprovoked episodes of inflammation, without the high-titer autoantibodies or antigen-specific T cells commonly seen in autoimmune diseases such as systemic lupus erythematosus or rheumatoid arthritis. Whereas the autoimmune diseases are disorders of the adaptive immune system, with its lymphocyte effector cells and receptors that somatically rearrange and mutate, the autoinflammatory diseases largely represent disorders of the phylogenetically more primitive innate immune system, mediated by myeloid effector cells and germline-encoded receptors. The autoinflammatory diseases can cause an intense acute phase response with elevation of the erythrocyte sedimentation rate, C-reactive protein, and serum amyloid A, in some cases leading to amyloid A (AA) amyloidosis (see Chapter 164).

The hereditary periodic fever syndromes include 2 illnesses with an autosomal recessive mode of inheritance, familial Mediterranean fever (FMF; MIM249100) and the hyperimmunoglobulinemia D with periodic fever syndrome (HIDS; MIM260920). Hereditary periodic fever syndromes with an autosomal dominant mode of inheritance include the tumor necrosis factor (TNF) receptor-associated periodic syndrome (TRAPS; MIM191190) and a spectrum of disorders known as the cryopyrin-associated periodic syndromes (CAPSs), or cryopyrinopathies. From mildest to most severe, CAPS includes the familial cold autoinflammatory syndrome (FCAS1; MIM120100), Muckle-Wells syndrome (MWS; MIM191100), and neonatal-onset multisystem inflammatory disease (NOMID; MIM607115) (also known as chronic infantile neurologic cutaneous and articular syndrome, or CINCA) (Table 163-1).

There are a number of other mendelian autoinflammatory diseases that present in childhood and are not considered hereditary periodic fever syndromes. These include the syndrome of pyogenic arthritis with pyoderma gangrenosum and acne (PAPA; MIM604416), deficiency of the interleukin 1 (IL-1) receptor antagonist (DIRA; MIM612852), Blau syndrome (also known as early-onset sarcoidosis; MIM186580), chronic atypical neutrophilic dermatosis with lipodystrophy and elevated temperature (CANDLE; MIM256040), autoinflammation with phospholipase Cγ2-associated antibody deficiency and immune dysregulation (APLAID; MIM614878), and deficiency of adenosine deaminase-2 (DADA2) (Table 163-2). Other disorders include congenital sideroblastic anemia with B-cell immunodeficiency, periodic fevers and developmental delay (SIFD) due to biallelic mutations of the TRNT1 gene as well as disease produced by mutations in the phospholipase Cγ2 gene (cold-induced urticaria, granulomatous rash, bronchiolitis, enterocolitis, eye inflammation) or by mutations in the cat-eye syndrome chromosome region, candidate 1 (CECR1) causing fever, stroke, rash, and vasculitis. An interferonopathy due to upregulation of TMEM173 that encodes STING (stimulation of

*Duration may vary; this is a typical duration.

Clinical Grouping of Autoinflammatory Diseases by Fever and Skin Manifestations

1. Nonspecific maculopapular rashes with recurrent episodic fever and abdominal pain (the classic “periodic fever syndromes”)
   - Recurrent fever attacks of short duration (typically <7 days)
     - FMF: familial Mediterranean fever
     - HIDS: mevalonate kinase deficiency/hyperimmunoglobulinemia D with periodic fever syndrome
   - Recurrent fever attacks of longer duration (typically >7 days)
     - TRAPS: TNF receptor-associated periodic fever syndrome

2. Neutrophilic urticaria (the cryopyrinopathies)
   - Recurrent fever attacks of short duration (typically <24 hr)
     - CAPS/FCAS: familial cold autoinflammatory syndrome
     - CAPS/MWS: Muckle-Wells syndrome

Continuous low-grade fever
   - CAPS/NOMID: neonatal onset multisystem inflammatory disease (NOMID)/chronic infantile neurologic cutaneous and articular syndrome (CINCA)

3. Granulomatous skin lesions and minimal or low-grade fever attacks
   - Blau syndrome/early-onset sarcoidosis (pediatric granulomatous arthritis)

4. Pustular skin rashes and episodic fever
   - With inflammatory bone disease
     - DIRA: deficiency of interleukin-1 receptor agonist
     - Majeed syndrome
   - With pyogenic arthritis
     - PAPA: pyogenic arthritis, pyoderma gangrenosum, and acne syndrome
   - With inflammatory bowel disease
     - Early-onset inflammatory bowel disease
     - Without other organ involvement
     - DITRA: deficiency of interleukin-36-receptor antagonist
   - CAMPS: CARD14-mediated psoriasis

5. Atypical neutrophilic dermatosis with histiocytic-like infiltrate
   - PRAAS: proteasome associated autoinflammatory syndromes

6. Syndromes with autoinflammation and immunodeficiency
   - PLAIlig: PLCγ-associated antibody deficiency and immune dysregulation
   - APLAID: autoinflammation and PLCγ-associated antibody deficiency and immune dysregulation
   - HOIL-1 deficiency

FAMILIAL MEDITERRANEAN FEVER
FMF is a recessively inherited autoinflammatory disease usually characterized by recurrent 1-3 day self-limited episodes of fever, serositis, mono- or pauciarticular arthritis, or an erysipелoidal rash, sometimes complicated by AA amyloidosis.

Etiology
FMF is caused by mutations in MEFV, a 10 exon gene located on the short arm of chromosome 16 encoding a 781 amino acid protein denoted pyrin (from the Greek for fever). Pyrin is expressed in granulocytes, monocytes, and dendritic cells, and in peritoneal, synovial, and dermal fibroblasts. The N-terminal ~90 amino acids of pyrin are the prototype for a motif (the PYRIN domain) that mediates protein-protein interactions and is found in more than 20 different human proteins that regulate inflammation and apoptosis. Through PYRIN-domain interactions, pyrin can activate caspase-1, the enzyme that converts the 31 kDa pro–IL-1β molecule into the biologically active 17 kDa IL-1β, which is a major mediator of fever and inflammation.

Many of the FMF-associated mutations in pyrin are found at the C-terminal B30.2 domain of pyrin, encoded by exon 10 of MEFV. More than 50 such FMF mutations are listed in an online database (http://fmf.igh.cnrs.fr/ISSAID/infevers/), nearly all of which are missense substitutions. Homozygosity for the M694V mutation may be associated with an earlier age of onset, arthritis, and an increased risk of amyloidosis. The substitution of glutamine for glutamic acid at residue 148 (E148Q), is considered to be either a mild mutation or a functional polymorphism in the pyrin protein. The combined frequencies of FMF mutations among several Mediterranean populations are extraordinarily high (up to 1:3), suggesting the possibility of a heterozygote advantage. It is also noteworthy that there is a small percentage of patients of typical ethnicity and the clinical findings of FMF who have no demonstrable MEFV mutations, suggesting the possibility of a second FMF locus.

Epidemiology
FMF occurs primarily among ethnic groups of Mediterranean ancestry, most commonly Jews, Turks, Armenians, Arabs, and Italians. Owing to a higher frequency of the M694V mutation, FMF is more severe and more readily recognized in the Sephardic (North African) than the Ashkenazi (East European) Jewish population. Nevertheless, due to demographics, most Jewish FMF patients in the US are of Ashkenazi ancestry. With the advent of genetic testing, mutation-positive FMF has been documented worldwide, although at lower frequency than in the Mediterranean basin and Middle East. Most patients present with symptoms in childhood, with 90% of patients presenting prior to the age of 20 yr.

Pathogenesis
It appears that FMF mutations lead to a gain-of-function and IL-1β-dependent inflammation, with a gene-dosage effect. These results may explain why many heterozygous carriers of FMF mutations have biochemical evidence of inflammation, why as many as 30% of symptomatic FMF patients have only 1 demonstrable MEFV mutation, and why IL-1 inhibitors have a therapeutic effect in FMF.

Clinical Manifestations

Clinical features of FMF may include fever, serositis presenting as pleuritic chest pain or severe abdominal pain, arthritis, and rash. The pleural pain is typically unilateral, whereas the abdominal pain can be generalized or localized to 1 quadrant, similar to other forms of peritonitis. FMF-associated arthritis occurs primarily in the large joints, may be accompanied by large, neutrophil-rich effusions, and is usually nonerosive and nondestructive. The hallmark cutaneous finding is an erysipelasoid erythematous rash that overlies the ankle or dorsum of the foot (Fig. 163-3). Other clinical findings include scrotal pain caused by inflammation of the tunica vaginalis testis, febrile myalgia, exercise-induced myalgia (particularly common in children), and an association with various forms of vasculitis, including Henoch-Schönlein purpura in as many as 5% of pediatric patients. FMF episodes may be triggered by stress, menses, or infections. Between flares, patients are generally symptom-free but may have persistent elevation of their inflammatory markers. The attack frequency can vary from weekly to 1-2 flares/year.

Diagnosis

The diagnosis of FMF can often be made clinically, paying special attention to the duration and recurrence of episodes, documentation of fever, the characteristic serositis, synovitis, or erysipelasoid rash, responsiveness to daily colchicine prophylaxis, and the absence of other causative factors. The differential diagnosis includes other hereditary periodic fever syndromes, and, depending on the specific circumstances, may include PFAPA, systemic-onset juvenile idiopathic arthritis (Still disease), cyclic hematopoiesis, gynecologic disorders (when abdominal pain predominates), porphyria, hereditary angioedema, septic arthritis, and the crystalline arthropathies.

Genetic testing can be used as adjunctive evidence in ambiguous cases, and in circumstances in which the clinician has little experience with FMF or related conditions. Although FMF is often regarded as a recessively inherited disorder, with the attendant expectation that patients will have 2 mutations in trans, it should be noted that in some series as many as 30–50% of patients with typical FMF, responsive to colchicine, have only a single demonstrable mutation, and a small percentage have no identifiable MEFV mutation. The interpretation of genetic testing may be further complicated by the presence of complex alleles in which 2 mutations may be found in cis (usually an exon 10 mutation with E148Q in exon 2).

Treatment

Prophylactic daily oral colchicine decreases the frequency, duration, and intensity of FMF flares. This regimen also prevents the development of systemic AA amyloidosis. Colchicine is generally well-tolerated and safe in children, with the most common side effects being diarrhea and other gastrointestinal complaints. Some patients develop lactose intolerance while taking colchicine. Gastrointestinal side effects can be minimized by initiating therapy at a low dose (for young children, 0.3 mg/day) and slowly titrating upward. A dose-related transaminitis may also be observed; bone marrow suppression is rarely seen at the dosages prescribed for FMF. Pediatric patients may require doses of colchicine similar to those needed in adults (1-2 mg/day), reflecting the fact that children metabolize the drug more rapidly than adults. It is not always possible to find a tolerated dose of colchicine at which all

      ix. Humidifier lung, polymer fume fever
   c. Neoplastic
      i. Lymphoma (e.g., Hodgkin disease, angioimmunoblastic lymphoma)
      ii. Solid tumor (e.g., pheochromocytoma, myxoma, colon carcinoma)
   d. Vascular (e.g., recurrent pulmonary embolism)
   e. Hypothalamic
   f. Psychogenic periodic fever
   g. Factitious or fraudulent

**Complications and Prognosis**

Amyloidosis is the most serious complication of FMF, and in its absence FMF patients may live a normal life span. Amyloidosis may develop when serum AA, an acute-phase reactant found at extremely high levels in the blood during FMF attacks, is cleaved to produce a 76 amino acid fragment that misfolds and deposits ectopically, most commonly in the kidneys, gastrointestinal tract, spleen, lungs, testes, thyroid, and adrenals. Rarely, cardiac amyloidosis may develop; macroglossia and amyloid neuropathy are generally not seen with the amyloidosis of FMF. The most common presenting sign of AA amyloidosis is proteinuria. The diagnosis is then usually confirmed by rectal or renal biopsy. There are a small number of case reports, mostly from the Middle East, in which amyloidosis may actually precede overt FMF attacks, presumably because of subclinical inflammation.

Risk factors for the development of amyloidosis in FMF include homozygosity for the M694V MEFV mutation, polymorphisms of the serum AA gene (encoding AA), noncompliance with colchicine treatment, male gender, and a positive family history of AA amyloid. For reasons that are unclear, country of origin is also a major risk factor for amyloidosis in FMF; with patients raised in the Middle East having a much higher risk than genotypically identical patients raised in the West. Aggressive lifelong suppression of the acute phase reactants should be the goal in patients with FMF amyloidosis, and there are documented cases in which this may result in resorption of amyloid deposits. The natural history of untreated amyloidosis in FMF is the inexorable progression to renal failure, often within 3–5 yr.
HYPERIMMUNOGLOBULINEMIA D WITH PERIODIC FEVER SYNDROME

HIDS, also known as mevalonate kinase deficiency, was initially described in a cohort of Dutch patients and occurs primarily in patients of Northern European descent. HIDS is recessively inherited and caused by mutations of MVK, a gene located on the long arm of chromosome 12 that encodes mevalonate kinase (MK). HIDS-associated mutations are distributed throughout the MK protein, but the 2 most common mutations are the substitution of isoleucine for valine at residue 377 (V377I), a variant that is quite common in the Dutch population, and the substitution of threonine for isoleucine at residue 268 (I268T).

MK is expressed in multiple tissues, and catalyzes the conversion of mevalonic acid to 5-phosphomevalonic acid in the biosynthesis of cholesterol and nonsterol isoprenoids. Patients with HIDS-associated mutations have markedly reduced, but not absent, MK enzymatic activity. HIDS patients usually have low-normal serum cholesterol levels, but the deficiency of isoprenoids may cause increased IL-1β production by aberrant activation of the small guanosine triphosphatase Rac1. Temperature elevation may further exacerbate this process by more complete inhibition of MK activity, leading to a possible positive feedback loop. Complete genetic deficiency of MK results in a more severe phenotype known as mevalonic aciduria (see Chapter 85).

The clinical features of HIDS generally appear within the 1st 6 mo of life. Febrile attacks last between 3 and 7 days with abdominal pain that is often accompanied by diarrhea, nausea, and vomiting. Other clinical manifestations include cervical lymphadenopathy, diffuse macular rash, pyoderma gangrenosum, and acne; TRAPS, tumor necrosis factor receptor-associated periodic syndrome. (From Simon A, van der Meer JWM, Drenth JPH: Familial autoinflammatory syndromes. In Firestein GS, Budd RC, Gabriel SE, et al, editors: Kelley's textbook of rheumatology, ed 9, Philadelphia, 2012, Saunders, Fig. 97-2.)
increased serum levels of acute-phase reactants and proinflammatory cytokines are commonly present.

The symptoms of HIDS may persist for years but tend to become less prominent in adulthood. Patients with HIDS usually have a normal life span. Unlike FMF and TRAPS, the incidence of AA amyloidosis is quite low. Standards for the treatment of HIDS are evolving. Very few
ASSOCIATED PERIODIC SYNDROME

Like FMF and HIDS, TRAPS is characterized by recurrent fevers and localized inflammation, but it is inherited in an autosomal dominant fashion and has a number of distinguishing clinical and immunologic features. TRAPS was first recognized in patients of Irish descent and denoted familial Hibernian fever to draw a contrast with FMF, but the current nomenclature was proposed when mutations in TNFRSF1A were discovered not only in the original Irish family, but in families from a number of other ethnic backgrounds. TNFRSF1A is located on the short arm of chromosome 12, and encodes the 55 kDa receptor (denoted p55, TNFR1, or CD120a) for TNF that is widely expressed on a number of cell types. A second 75 kDa receptor largely restricted to leukocytes is encoded on chromosome 1.

TRAPS was originally defined as an autoinflammatory disorder resulting from TNFRSF1A mutations, and thus genetic testing is required to make the diagnosis. To date, more than 90 disease-associated TNFRSF1A mutations are listed on the online Infesrs database, as well as a smaller number of variants of unknown significance. Nearly all of the TRAPS-associated mutations in are in the extracellular domain of the TNFR1 protein, with about one-third involving the substitution of another amino acid for a highly conserved cysteine residue, thus disrupting disulfide bonds and leading to protein misfolding. A number of other missense mutations not involving cysteine residues have been shown to have a similar effect on TNFR1 protein folding. Misfolded TNFR1 aggregates intracellularly and leads to constitutive signaling through mitogen-activated protein kinases, resulting in the release of proinflammatory cytokines such as IL-1β and TNF-α. The substitution of glutamine for arginine at residue 92 (R92Q) and the substitution of leucine for proline at residue 46 (P46L) are seen in greater than 1% of the white and African-American populations, respectively. These variants do not lead to the same biochemical or signaling abnormalities seen with more-severe TRAPS mutations, and, like E148Q in FMF, there is debate as to whether they are mild mutations or functional polymorphisms.

Patients with TRAPS typically present within the 1st decade of life. Flares can occur with variable frequency but the duration is often substantially longer when compared to FMF or HIDS flares. The febrile episodes of TRAPS last at least 3 days and can persist for weeks at a time. As in FMF, there may be pleural and/or peritoneal involvement. At times patients present with signs of an acute abdomen; on exploration such patients have sterile peritonitis, sometimes with adhesions from previous episodes. Patients may also have nausea and frequently report constipation at the onset of flares that progresses to diarrhea by the conclusion. Ocular signs include periorbital edema and conjunctivitis. TRAPS patients may also experience severe myalgia and on imaging the muscle groups may have focal areas of edema. There are a number of rashes that can be seen in TRAPS patients, but the most common is an erythematous macular rash that on biopsy contains superficial and deep perivascular infiltrates of mononuclear cells. Patients often report that the rash migrates distally on a limb during its course with an underlying myalgia and can resemble cellulitis. Other rashes include erythematous annular patches as well as a serpiginous rash (Fig. 163-7). Approximately 10-15% of patients with TRAPS may develop AA amyloidosis; the presence of cysteine mutations and a positive family history are risk factors for this complication. If amyloidosis does not develop, TRAPS patients have a normal life expectancy.

Colchicine is generally not effective in TRAPS. For relatively mild disease, nonsteroidal anti-inflammatory agents may suffice. For more severe disease with infrequent attacks, corticosteroids at the time of an attack may be effective, but it is not unusual for steroid requirements to increase over time. Because some patients with TRAPS exhibit a defect in activation-induced TNF receptor shedding, and have diminished levels of immune modulatory soluble TNFR in the blood, etanercept, the soluble p75 TNFR:Fc fusion protein has been studied in this disorder. Etanercept is often effective in reducing the severity and frequency of flares, but longitudinal follow-up of TRAPS patients treated with etanercept indicates waning efficacy with time. Of note, treatment of TRAPS with anti-TNF monoclonal antibodies has sometimes led to a paradoxical worsening of disease. Experience with both anakinra, a recombinant IL-1 receptor antagonist, and canakinumab, a monoclonal anti–IL-1β antibody, has been favorable in TRAPS patients.

patients respond to colchicine; milder disease may respond to nonsteroidal antiinflammatory drugs. Corticosteroids are of limited utility. Small trials of both etanercept and either intermittent or daily anakinra in HIDS are promising.

THE TUMOR NECROSIS FACTOR RECEPTOR-ASSOCIATED PERIODIC SYNDROME

Like FMF and HIDS, TRAPS is characterized by recurrent fevers and localized inflammation, but it is inherited in an autosomal dominant

Figure 163-5 Petechiae on the leg of a hyper-IgD syndrome patient during a febrile attack. (From Simon A, van der Meer JWM, Drenth JPH: Familial autoinflammatory syndromes. In Firestein GS, Budd RC, Gabriel SE, et al, editors: Kelley’s textbook of rheumatology, ed 9, Philadelphia, 2012, Saunders, Fig. 97-7.)

Figure 163-6 Aphthous ulceration detected on the tongue of a patient with hyper-IgD syndrome. (Courtesy Dr. K. Antila, North Carelian Central Hospital, Joensuu, Finland; from Simon A, van der Meer JWM, Drenth JPH: Familial autoinflammatory syndromes. In Firestein GS, Budd RC, Gabriel SE, et al, editors: Kelley’s textbook of rheumatology, ed 9, Philadelphia, 2012, Saunders, Fig. 97-8.)
CRYOPYRIN-ASSOCIATED PERIODIC FEVER SYNDROMES

CAPS represents a spectrum of clinical disorders, including FCAS, MWS, and NOMID/CINCA. Although 3 separate clinical diagnoses have been defined, it should be emphasized that the cryopyrinopathies are really a continuum, and that patients may present with overlap syndromes that do not fit neatly into a single diagnosis. This spectrum of illness is caused by mutations in NLRP3 (formerly known as CIAS1), located on the long arm of chromosome 1, which encodes a protein variously denoted cryopyrin or NLRP3. More than 100 disease-associated NLRP3 mutations have been enumerated on the Infevers online database. Advances in next-generation sequencing have also permitted the identification of symptomatic individuals with somatic NLRP3 mosaicism.

NLRP3 is a PYRIN domain-containing protein that is strongly expressed in myeloid cells, and to a lesser degree in other tissues. It is a part of a macromolecular complex termed the NLRP3 inflammasome that activates pro–IL-1β to its mature form in response to a variety of endogenous danger-associated molecular patterns and pathogen-associated molecular patterns. Patients with cryopyrinopathies have gain-of-function mutations in NLRP3 that result in constitutive or easily-triggered activation of the NLRP3 inflammasome.

The cryopyrinopathies are characterized by recurrent fevers and an urticaria-like rash that develops early in infancy (Fig. 163-8). Histopathologic examination reveals a perivascular neutrophilic infiltrate without the mast cells or mast cell degranulation seen with true urticaria. In patients with FCAS, febrile attacks generally begin 1-3 hr after generalized cold exposure. FCAS patients also experience polyarthralgia of the hands, knees, and ankles, and conjunctivitis may also develop during attacks. FCAS episodes are self-limited and generally resolve within 24 hr. AA amyloidosis rarely occurs in FCAS.

In contrast to FCAS, the febrile episodes of MWS are not cold-induced, but are characterized by the same urticarial rash seen in FCAS (Fig. 163-9). Many MWS patients also develop progressive sensorineural hearing loss, and, untreated, approximately 30% of MWS patients develop AA amyloidosis. NOMID patients present in the neonatal
period with a diffuse, urticarial rash, daily fevers, and dysmorphic features. Significant joint deformities, particularly of the knees, may develop because of bony overgrowth of the epiphyses of the long bones (Figs. 163-10 and 163-11). NOMID patients also develop chronic aseptic meningitis, leading to increased intracranial pressure, optic disc edema, visual impairment, progressive sensorineural hearing loss, and intellectual disability (Fig. 163-12). Because of the severe disabilities associated with untreated NOMID, this disorder appeared to be sporadic before NLRP3 mutations were identified in these patients.

Targeted therapy with anakinra, a recombinant IL-1 receptor antagonist, has been life-changing for NOMID patients, not only controlling fever and rash, but also preventing end-organ damage. Anakinra was FDA-approved for NOMID. Rilonacept, a soluble IL-1 receptor decoy, and canakinumab, a long-acting, fully humanized IgG1 anti–IL-1β monoclonal antibody, are effective in both FCAS and MWS, and are FDA-approved for both conditions. Aggressive IL-1 blockade has resulted in attenuation of amyloidosis in the cryopyrinopathies.

OTHER MENDELIAN AUTOINFLAMMATORY DISEASES

The Syndrome of Pyogenic Arthritis with Pyoderma Gangrenosum and Acne

PAPA syndrome is a rare autosomal dominant disorder caused by mutations in PSTPIP1, a gene located on chromosome 15 that encodes the cytoskeletal proline serine threonine phosphatase-interacting (PSTPIP) protein. The PSTPIP1 protein interacts with a number of immunologically important molecules, including CD2, the Wiskott-Aldrich syndrome protein (WASP), and pyrin. PAPA-associated PSTPIP1 mutations markedly increase its affinity to pyrin and cause increased IL-1β production.

Clinical manifestations of PAPA syndrome include recurrent episodes of sterile, pyogenic arthritis that leads to erosions and joint destruction, and appears to develop spontaneously or after minor trauma. The onset of arthritis is often in early childhood. Cutaneous manifestations tend to develop in adolescence, at which time patients are prone to developing severe cystic acne. Additionally, PAPA patients commonly develop ulcerating pyoderma gangrenosum lesions (Fig. 163-13), and some develop pathergy reactions.

The treatment of PAPA syndrome may involve the use of corticosteroids, IL-1 antagonists, and TNF inhibitors, sometimes in combination. The joint manifestations of PAPA appear to respond to IL-1
Blau syndrome is a rare autosomal dominant disorder that manifests as early-onset granulomatous arthritis, uveitis, and rash. The arthritis may affect the ankles and wrists, and may lead to flexion contractures of the fingers and toes (camptodactyly). Early-onset sarcoidosis presents with a similar clinical picture, sometimes with visceral involvement, and both conditions are caused by mutations in CARD15/
NOD2 on chromosome 16. The protein encoded by this gene, variously denoted caspase recruitment domain protein 15 or nucleotide-binding oligomerization domain 2 protein, is an intracellular sensor of bacterial products in dendritic cells, myelomonocytic cells, and Paneth cells. Mutations in the NOD2 oligomerization domain of this protein cause Blau syndrome/early-onset sarcoidosis, while variants primarily in the leucine-rich repeat domain of this protein are associated with susceptibility to Crohn disease. Corticosteroids have been the mainstay of therapy for Blau syndrome. There are a number of case reports of the beneficial effects of TNF inhibitors, in Blau syndrome.

Chronic Atypical Neutrophilic Dermatosis with Lipodystrophy and Elevated Temperature

CANDLE is an autosomal recessive disease resulting from mutations in PSMB8. This gene encodes the β5i subunit of the immunoproteasome, a macromolecular complex that degrades proteins in immune cells for presentation on major histocompatibility complex class I molecules. Disease-associated mutations result in a loss of function. Patients present in the 1st yr of life with recurrent fevers, violaceous swollen eyelids, purpuric skin lesions with a mixed mononuclear and neutrophilic infiltrate, arthralgia, delayed physical development, and anemia. Acute-phase reactants are also elevated in these patients and, over time, they develop progressive lipodystrophy. On gene expression profiling, CANDLE patients have a robust interferon signature. There is no established treatment for CANDLE, although the interferon pathway may represent a therapeutic target. Two other disorders, Nakajo-Nishimura syndrome and the syndrome of joint contractures, muscular atrophy, myocytic anemia, and panniculitis-induced lipodystrophy, are clinically similar to CANDLE and are also caused by mutations in PSMB8.

Autoinflammation with Phospholipase Cγ2-Associated Antibody Deficiency and Immune Dysregulation

APLAID is a dominantly-inherited disorder characterized by recurrent blistering skin lesions, bronchiolitis, arthralgia, ocular inflammation, enterocolitis, absence of autoantibodies, and mild immunodeficiency. It is caused by gain-of-function mutations in PLCG2, leading to increased signaling through the phospholipase Cγ pathway in immune cells. To date there is no established therapy for APLAID.

Deficiency of Adenosine Deaminase 2

DADA2 is an autoinflammatory disorder caused by loss-of-function mutations in CECLI, encoding adenosine deaminase 2, characterized by recurrent fevers and a spectrum of vascular manifestations that includes livedo racemosa, early-onset ischemic lacunar strokes, and polyarteritis nodosa. Patients may also present with hepatosplenomegaly and a mild immunodeficiency. ADA2 is a protein produced primarily by monocytes and macrophages, which appear to act as a growth factor both for endothelial cells and for the antiinflammatory M2 subset of macrophages. Patients experience a vicious circle of vasculopathy and inflammation. Although there is no established therapy, there is anecdotal evidence supporting the use of etanercept.

GENETICALLY COMPLEX AUTOINFLAMMATORY DISEASES

**Periodic Fever, Aphthous Stomatitis, Pharyngitis, and Adenitis (PFAPA)**

PFAPA is the most common recurrent fever syndrome in children. It usually presents between the ages of 2 and 5 yr with recurring episodes of fever, malaise, exudative-appearing tonsillitis with negative throat cultures, cervical lymphadenopathy, oral aphthae, and, less commonly, headache, abdominal pain, and arthralgia. The episodes last 4-6 days, regardless of antipyretic or antibiotic treatment, and often occur with clock-like regularity on 3-6 wk cycles. Findings during the episodes may include mild hepatosplenomegaly, mild leukocytosis, and elevated acute-phase reactants. Both the frequency and the intensity of the episodes diminish with increasing age.

The etiology and pathogenesis of PFAPA remain unknown. The majority of patients show dramatic response to a single oral dose of prednisone (0.6-2.0 mg/kg), although this approach does not prevent recurrence and may actually shorten the interval between flares. Cimetidine given at doses of 20-40 mg/kg/day is effective at preventing recurrences in approximately one-third of cases. Complete resolution has also been reported after tonsillectomy in some but not all patients. A pilot study of anakinra (1 mg/kg subcutaneously) given for 1-2 days at the onset of symptoms showed promising results.

**Chronic Recurrent Multifocal Osteomyelitis (CRMO)**

CRMO is a form of inflammatory bone disease most commonly seen in children (see Table 163-3). Histologically and radiologically, CRMO is virtually indistinguishable from infectious osteomyelitis. Patients typically present with bone pain and may also have fever, soft-tissue swelling, and elevated acute-phase reactants. Cultures are sterile. The etiology of sporadic CRMO is unknown. Rarely CRMO can occur with congenital dyserythropoietic anemia (Majeed syndrome), caused by mutations in LPIN2. CRMO has also been seen in association with inflammatory bowel disease and inflammatory skin disease such as palmoplantar pustulosis. There is evidence for reduced production of the antiinflammatory cytokine IL-10 in CRMO. Initial therapy includes nonsteroidal antiinflammatory medications. Second-line treatments include corticosteroids, TNF inhibitors, and bisphosphonates.

Bibliography

Amyloidosis comprises a group of diseases characterized by extracellular deposition of insoluble, fibrous amyloid proteins in various body tissues.

**ETIOLOGY**

Amyloidosis is a disease caused by protein misfolding. These misfolded proteins infiltrate, aggregate, and form insoluble fibrils that can affect the normal function of a number of vital organs.

In the amyloidosis nomenclature, there is a distinction made between amyloidosis that develops from mutations in the amyloid fibril protein itself versus amyloidosis associated with genetic mutation in nonamyloid proteins. The former are referred to as hereditary amyloidoses; examples include mutations in the genes for transthyretin and apolipoprotein A, both of which are uncommon in children. This is in contrast to amyloid A (AA) amyloidosis, which develops in patients with chronic inflammatory states. It is estimated that, worldwide, approximately 45% of all amyloid cases are AA amyloidosis. In the past, chronic infectious diseases such as tuberculosis, malaria, leprosy, and chronic osteomyelitis accounted for most cases of AA amyloidosis. With effective treatment for these infections, other causes of AA have become more common. A number of chronic inflammatory rheumatic diseases such as rheumatoid arthritis (RA), juvenile idiopathic arthritis (JIA), ankylosing spondylitis, as well as hereditary autoinflammatory diseases, have an increased risk for the development of AA amyloidosis. AA amyloidosis has also been associated with granulomatous diseases such as sarcoidosis, cystic fibrosis, Crohn disease, malignancies such as mesothelioma and Hodgkin diseases, intravenous drug abuse, and other infections, such as bronchiectasis and HIV. Approximately 6% of AA amyloidosis cases have no identified disease association. AL amyloidosis (formally known as idiopathic amyloidosis or myeloma-associated amyloidosis) is extremely rare in children, occurring in middle-aged or older individuals.

**EPIDEMIOLOGY**

Only AA amyloidosis affects children in appreciable numbers. The factors that determine the risk for amyloidosis as a complication of inflammation are not clear, because many individuals with longstanding inflammatory disease do not demonstrate tissue amyloid deposition, while some children with relatively recent onset of disease may develop amyloidosis. In developed countries, priorit to the initiation of therapy with disease-modifying anti-rheumatic drugs (DMARDs) and biologic agents, RA was the most common inflammatory disease associated with AA amyloidosis. Patients who had a long history of poorly controlled severe disease with extraarticular manifestations were the most at risk for developing amyloidosis and the median time from first symptoms of their rheumatic condition to the diagnosis of amyloidosis was 212 mo. The full effect of DMARD and biologic therapy in RA-associated amyloidosis has yet to be fully appreciated, but studies are showing a sustained decline in the number of new cases.

JIA is another rheumatic disease that is associated with the development of AA amyloidosis with the highest prevalence in patients with systemic JIA followed by those with polyarticular disease (see Chapter 155). In the pre-DMARD and biologic era, the prevalence of AA amyloidosis in JIA patients ranged from 1-10%. Higher prevalence was seen in Northern European patients, especially Polish patients who had a prevalence of 10.6%; lower prevalence was observed in North America. The reasons for this discrepancy are not completely understood although it is speculated that selection bias, genetic background, and tendency toward more early aggressive therapy in North Americans may have played a role.

The hereditary autoinflammatory diseases define a group of illnesses that are characterized by attacks of seemingly unprovoked recurrent inflammation without significant levels of either autoantibodies or antigen-specific T cells, which are typically found in patients with autoimmune diseases (see Chapter 163). Whereas autoimmune diseases such as systemic lupus erythematosus and RA result from a derangement in the adaptive immune system, the autoinflammatory syndromes are a result of malfunctions in the innate immune system. The inflammatory attacks are mediated by cells of the innate immune system (neutrophils and macrophages). Although seemingly unprovoked, these attacks are often initiated by stress, immunization, or trauma, suggesting that gene–environment interactions play an important role in pathogenesis. Although there is some variability among the autoinflammatory diseases, common findings include fevers, cutaneous rashes, arthritis, serositis, and ocular involvement. The inflammatory attacks are accompanied by intense acute phase responses (erythrocyte sedimentation rate and C-reactive protein) and high levels of serum amyloid A (SAA). Amyloidosis AA is associated with some but not all the hereditary autoinflammatory diseases.

**Familial Mediterranean fever (FMF)** is the most common of the mendelian autoinflammatory diseases and is seen most frequently in the Armenian, Arab, Turkish, and Sephardi Jewish populations. FMF is an autosomal recessive disease that results from mutations in the MEFV gene, which encodes the pyrin/marenostrin protein. MEFV mutations affecting the M680 and M694 amino acid residues are associated with early onset of FMF, severe disease, and an increased risk of AA amyloidosis. Patients residing in Armenia, Turkey, and Arabian countries have an increased risk of developing AA amyloidosis compared to patients with the same mutations of MEFV living in North America.

**Tumor necrosis factor receptor associated periodic syndrome (TRAPS)** is associated with mutations in the TNFRSF1A gene, which encode the 55 kDa tumor necrosis factor (TNF) receptor protein (TNFR1). It is estimated that 14-25% of patients with TRAPS develop AA amyloidosis. Patients with mutations in TNFRSF1A that affect cysteine residues have the highest risk of developing AA amyloidosis. It is thought that these cysteine residues participate in assembly of disulfide bonds important for TNFR1 folding and disruption of these bonds affects protein folding.

Mutations in the NLRP3 gene (also known as CIAS1, cold-induced autoinflammatory syndrome 1) cause 3 clinically distinct diseases: familial cold autoinflammatory syndrome, Muckle-Wells syndrome (MWS), and neonatal onset multisystem inflammatory disease (NOMID) that is also known as chronic infantile neurologic cutaneous and articular (CINCA) syndrome. Mutations in NLRP3 are inherited in an autosomal dominant fashion or as de novo mutations in patients with the most severe disease. Familial cold autoinflammatory syndrome is generally the least severe of the cryopyrinopathies and is rarely associated with AA amyloidosis. MWS presents with fevers, myalgias, arthralgias, urticarial-like rash, and progressive sensorineural hearing loss. AA amyloidosis is quite common in MWS, affecting up to one-third of the patients. NOMID/CINCA is the most severe cryopyrinopathy. Historically 20% of patients died before reaching adulthood but with current therapies, many are living longer lives. There have been NOMID patients who develop AA amyloidosis as they get older, although cases are not as frequent as those with MWS, possibly due to a shortened life span in these patients.

**Hyper IgD syndrome (HIDS)** is another autoinflammatory disease that presents in early childhood with chills, high fevers, abdominal pain, lymphadenopathy, and occasional rash. HIDS is an autosomal recessive disease that involves loss of function mutations in the MVK gene that encodes the mevalonate kinase enzyme. Inflammatory markers, including SAA, are high during attacks and may remain elevated in the intercurrent period. AA amyloidosis is rare in HIDS but has been reported.

Although seen less frequently than in the hereditary periodic fever syndromes, the risk of AA amyloidosis has been well established in patients with Crohn disease. It is estimated that AA amyloidosis occurs in approximately 1% of patients in the United States and up to 3% in Northern European patients. Conversely, AA amyloidosis presenting
in patients with ulcerative colitis is extremely rare, with estimated prevalence of 0.07%. The patients have a long-standing history of aggressive, poorly controlled disease; however there are reports of amyloidosis in patients with well-controlled inflammatory markers.

**PATHOGENESIS**

The deposition of AA amyloid fibrils is a result of a prolonged inflammatory state that leads to misfolding of the AA amyloid protein and deposition into tissues. The precursor protein of the fibrils in AA amyloidosis is an apolipoprotein called SAA. SAA is produced in the liver in response to proinflammatory cytokines such as interleukin (IL)-1, IL-6, and TNF-α and can increase more than 1,000-fold during inflammation. It has been speculated that SAA has a role as a chemoattractant and in lipid metabolism. Supporting this theory is the finding that amyloid deposition occurs initially in organs that are major sites of lipid and cholesterol metabolism such as the kidney, liver, and spleen.

Under normal circumstances SAA is secreted by the liver and completely degraded by macrophages. The secreted SAA protein is 104 amino acids in length and is primarily secreted in an α-helix structure. For reasons not completely understood, patients with AA amyloidosis have a flaw resulting in incomplete degradation and accumulation of intermediate SAA products. In these patients, SAA is transferred to the lysosome where the c-terminal portion of the SAA protein is cleaved, allowing the remaining protein to fold into a β-pleated sheet configuration. Deposited amyloid contains only 66-76 amino acids compared to the 104 in secreted SAA. These cleaved fragments polymerize and form fibrils that are deposited in the extracellular space and bind proteoglycans and other proteins such as serum amyloid P. These fibrils then become resistant to proteolysis and deposit in organ tissues.

**CLINICAL MANIFESTATIONS**

Although organ involvement may vary, AA amyloidosis most commonly affects the kidneys; 90% of patients have some degree of renal involvement. Unexplained proteinuria may be the presenting feature in some patients. Nephrotic syndrome and renal failure may develop if the underlying inflammatory condition is not controlled or if diagnosis is delayed. Median survival after diagnosis has been reported to be 133 mo; patients with higher SAA levels had significantly higher risk of death than those with lower SAA levels. Gastrointestinal involvement is seen in approximately 20% of patients and usually manifests as chronic diarrhea, gastrointestinal bleeding, abdominal pain, and malabsorption, whereas testes are frequently involved (87%).

Relatively uncommon findings associated with AA amyloidosis include anemia, amyloid goiter, hepatomegaly, splenomegaly, adrenal involvement, and pulmonary involvement. Tissues, such as the heart, tongue, and skin, are rarely involved.

**DIAGNOSIS**

The diagnosis of amyloidosis is established by biopsy demonstrating amyloid fibril proteins in affected tissues. The tissues most commonly tested include kidney, rectum, abdominal fat pad, and gingiva. Amyloid deposits are composed of seemingly homogeneous eosinophilic material that stains with Congo red dye and demonstrates the pathognomonic “apple-green birefringence” in polarized light. Amyloid can also be recognized with routine hematoxylin and eosin staining and electron microscopy.

**LABORATORY FINDINGS**

Patients with AA amyloidosis usually show elevated acute-phase reactants and high levels of immunoglobulins. Specific laboratory testing is possible only for AL amyloidosis, and most patients with this form of amyloidosis show increased plasma cells in the bone marrow and serum or urine monoclonal immunoglobulin (Ig) or free light chain. A biopsy showing amyloid deposition along with a monoclonal serum protein distinguishes AL amyloidosis from monoclonal gammopathy of uncertain significance, which is common in older adults.

**TREATMENT**

There is no established therapy to AA amyloidosis and, thus, the primary means of treatment of AA amyloidosis is aggressive management of the underlying inflammatory or infectious disease, which decreases levels of SAA protein. As newer therapies have been developed to treat the underlying condition, there is emerging evidence that the incidence of AA amyloidosis is decreasing. Colchicine is effective not only in controlling the attacks of FMF but also in preventing the development of amyloidosis associated with FMF. Children with FMF who are homozygous for the M694V mutation in the MEFV gene are at greater risk for development of amyloidosis and should be monitored closely.

Unlike AA amyloidosis associated with FMF, AA amyloidosis associated with other autoinflammatory diseases (including TRAPS, cryopyrin-associated periodic syndrome, and HIDS) and chronic rheumatic diseases (JIA, RA, and ankylosing spondylitis) do not respond to colchicine. Although AA amyloidosis associated with JIA may respond to chlorambucil, this drug is associated with chromosome breakage and a risk of subsequent malignancy.

Increasing use of biologic medicines against proinflammatory cytokines to treat RA, JIA, spondyloarthropathies, and the hereditary autoinflammatory diseases seems to impact risk factors for the development of AA amyloidosis. The class of medications referred to as the anti-TNF-α drugs have been paramount in the management of RA and other autoimmune disease. In both autoimmune and autoinflammatory conditions with accompanying AA amyloidosis, there are reports documenting the effectiveness of anti-TNF agents in blunting the progression of amyloidosis. Adverse effects of anti-TNF medications include reactivation of tuberculosis and hepatitis B, thus careful screening should be performed before instituting therapy. Additionally, the development of various antibodies, autoantibodies, and autoimmune disease has been noted in patients taking anti-TNF agents. Extreme caution should be used in prescribing anti-TNF agents to patients with a history of heart failure or demyelinating disease, as use can cause exacerbations in their underlying cardiac and neurologic diseases.

The IL-1 pathway is the target of multiple biologic medications used in autoimmune and autoinflammatory diseases. The 3 available IL-1 antagonists are anakinra (IL-1 receptor antagonist), rilonacept (soluble IL-1 receptor decoy), and canakinumab (long-acting fully humanized IgG1 anti–IL-1β monoclonal antibody). The various IL-1 inhibitors have been successful at slowing the progression of AA amyloidosis, and in some cases treatment results in regression of amyloid associated proteinuria.

Tocilizumab, an anti–IL-6 receptor antibody, has been shown to attenuate experimental AA amyloid and to reverse AA amyloidosis complicating JIA and RA. Eprodisate disodium is currently in international trial in patients with AA amyloidosis–associated nephropathy. By binding the amyloidigenic precursor proteins, eprodisate disodium attempts to prevent the deposition of amyloid in organ, hence preserving renal function.

**COMPLICATIONS AND PROGNOSIS**

End-stage renal failure is the underlying cause of death in 40-60% of patients with amyloidosis, with a median survival time from diagnosis of 2-10 yr. According to a large-scale study of 374 patients with AA amyloidosis, the factors associated with a poor prognosis include older age, a lower albumin serum level, end-stage renal disease at baseline, and prolonged serum elevation of SAA. An elevated SAA value was the most powerful risk factor for end-stage renal disease and death from AA amyloidosis.

**PREVENTION**

The primary means of preventing AA amyloidosis is treatment of the underlying inflammatory or infectious disease, resulting in decreases in the level of SAA protein and the risk of amyloid deposition. Although the period of latency between the onset of inflammation (of the underlying disease) and the initial clinical signs of AA amyloidosis may vary and is often prolonged, progression of the amyloid depositions can be rapid.

Bibliography is available at Expert Consult.
Bibliography

Sarcoidosis is a rare multisystem granulomatous disease of unknown etiology. The name is derived from a Greek word meaning "flesh-like condition," in reference to the characteristic skin lesions. There appear to be 2 age-dependent distinct patterns of disease among children with sarcoidosis. The clinical features in older children are similar to those in adults (pediatric onset adult sarcoidosis), with frequent systemic features (fever, weight loss, malaise), pulmonary involvement and lymphadenopathy. In contrast, early-onset sarcoidosis manifesting in children <4 yr of age is characterized by the triad of rash, uveitis, and polyarthritis.

ETIOLOGY

The etiology of sarcoidosis remains obscure but likely results from exposure of a genetically susceptible individual to 1 or more unidentified antigens. This exposure initiates an exaggerated immunologic response that ultimately leads to the formation of granulomas. The human major histocompatibility complex is located on chromosome 6, and specific human leukocyte antigen class I and class II alleles are associated with disease phenotype. Genetic polymorphisms involving various cytokines and chemokines may also have a role in development of sarcoidosis. Familial clustering supports the contribution of genetic factors to sarcoidosis susceptibility. Environmental and occupational exposures are also associated with disease risk. There are positive associations between sarcoidosis and agricultural employment, occupational exposure to insecticides, and moldy environments typically associated with microbial bioaerosols.

Blau syndrome is an autosomal dominant, familial form of sarcoidosis and is typified by the early onset of granulomatous inflammation involving the skin, eyes, and joints. Missense mutations in the CARD15/NOD2 gene on chromosome 16 have been found in affected family members and appear to be associated with development of sarcoidosis. The 2 most common amino acid substitutions are R334W (arginine to glutamine) and R334Q (arginine to tryptophan). Similar genetic mutations also have been found in individuals with a sporadic early-onset sarcoidosis (EOS) (rash, uveitis, arthritis), suggesting that this nonfamilial form and Blau syndrome are genetically and phenotypically identical (see Chapter 163).

EPIDEMIOLOGY

A nationwide patient registry of childhood sarcoidosis in Denmark estimated the annual incidence to be 0.22-0.27 per 100,000 children. The incidence increases with age, and peak onset occurs at 20-39 yr. The most common age of reported childhood cases is 13-15 yr. Annual incidence is about 11 per 100,000 in adult white Americans and is 3 times higher in African-Americans. There is no clear sex predominance in childhood sarcoidosis. Within the United States, the majority of childhood sarcoidosis cases are reported in the Southeastern and South Central states.

An international registry and Spanish cohort of Blau syndrome and EOS reported the mean age of disease onset as 30 mo and 36 mo, respectively. All but 3 of these young patients presented before 5 yr of age. There does not appear to be a sex preference in either condition.

PATHOLOGY AND PATHOGENESIS

Noncaseating, epithelioid granulomatous lesions are a cardinal feature of sarcoidosis. Activated macrophages, epithelioid cells, and multinucleated giant cells as well as CD4+ T lymphocytes accumulate and become tightly packed in the center of the granuloma. The causative agent that initiates this inflammatory process is not known. The periphery of the granuloma contains a loose collection of monocytes, CD4+ and CD8+ T lymphocytes, and fibroblasts. The interaction between the macrophages and CD4+ T lymphocytes is important in the formation and maintenance of the granuloma. The activated macrophages secrete high levels of tumor necrosis factor-α (TNF-α) and other proinflammatory mediators. The CD4+ T lymphocytes differentiate into type 1 helper T cells and release interleukin (IL)-2 and interferon-γ, promoting proliferation of lymphocytes. Granulomas may heal or resolve with complete preservation of the parenchyma. In approximately 20% of the lesions, the fibroblasts in the periphery proliferate and produce fibrotic scar tissue, leading to significant and irreversible organ dysfunction.

The sarcoid macrophage is able to produce and secrete 1,25-(OH)2-vitamin D or calcitriol, an active form of vitamin D typically produced in the kidneys. The hormone’s natural functions are to increase intestinal absorption of calcium and bone resorption and to decrease renal excretion of calcium and phosphate. An excess of calcitriol may result in hypercalcemia and hypercalciuria in patients with sarcoidosis.

CLINICAL MANIFESTATIONS

Sarcoidosis is a multisystem disease, and granulomatous lesions may occur in any organ of the body. The clinical manifestations depend on the extent and degree of granulomatous inflammation and are extremely variable. Children may present with nonspecific symptoms, such as fever, weight loss, and general malaise. In adults and older children, pulmonary involvement is most frequent, with infiltration of the thoracic lymph nodes and lung parenchyma. Isolated bilateral hilar adenopathy (Fig. 165-1) on chest radiograph is the most common finding, but parenchymal infiltrates and miliary nodules may also be seen (Fig. 165-2). Patients with lung involvement are commonly found to have restrictive changes on pulmonary function testing. Symptoms of pulmonary disease are seldom severe and generally consist of a dry, persistent cough.

Extrathoracic lymphadenopathy and infiltration of the liver, spleen, and bone marrow also occur often. Infiltration of the liver and spleen typically leads to isolated hepatomegaly and splenomegaly, respectively, but actual organ dysfunction is rare. Cutaneous disease, such as plaques, nodules, erythema nodosum in acute disease, or lupus pernio in chronic sarcoidosis, appears in one quarter of cases and is usually present at onset. Red-brown to purple maculopapular lesions < 1 cm
A chest radiograph of a 10-year-old girl with sarcoidosis showing widely disseminated peribronchial infiltrates, multiple small nodular densities, hyperaeration of the lungs, and hilar lymphadenopathy.

Figure 165-3 Sarcoidosis nodules on the face. (From Shah BR, Laude TA: Atlas of pediatric clinical diagnosis, Philadelphia, 2000, Saunders.)

In contrast to the variable clinical presentation of sarcoidosis in older children, Blau syndrome and EOS (NOD2-associated sarcoidosis) classically manifest as the triad of uveitis, arthritis, and rash. Pulmonary disease and lymphadenopathy are less common. The arthritis is polyarticular and symmetric, with large boggy effusions. Large and small joints are involved; tenosynovitis is an associated finding. Joints are stiff and moderately tender. The rash may wax and wane and is diffuse (mostly truncal), erythematous or tan, macular–papular, and often desquamates at times being confused with eczema or ichthyosis vulgaris. Tender subcutaneous nodules resembling erythema nodosum may be seen on the legs. Noncaseating granulomas are demonstrated with biopsy of the skin or joint synovium.

Granulomatous iridocyclitis and posterior uveitis may progress to panuveitis, which has a high risk for vision loss. Iris nodules, photophobia, erythema, cataracts, or glaucoma may be present or develop over time.

Patients with NOD2 mutations in particular display this more restricted phenotype but may also have visceral disease, whereas those without a NOD2 mutation often show extended manifestations, including fever, hepatosplenomegaly, lymphadenopathy, and lung, kidney, and CNS involvement.

Infantile onset panniculitis with uveitis and systemic granulomatosis is an uncommon manifestation of sarcoidosis. Sarcoidosis has also been reported in adults treated with type 1 interferons for hepatitis or multiple sclerosis.

LABORATORY FINDINGS

There is no single standard laboratory test diagnostic of sarcoidosis. Anemia, leukopenia, and eosinophilia may be seen. Other nonspecific findings include hypergammaglobulinemia and elevations in acute-phase reactants, including erythrocyte sedimentation rate and C-reactive protein value. Hypercalcaemia and/or hypercalciuria occur in only a small proportion of children with sarcoidosis. Angiotensin-converting enzyme (ACE) is produced by the epithelioid cells of the granuloma, and its serum value may be elevated, but this finding lacks diagnostic sensitivity and specificity. ACE levels are estimated to be elevated in more than 50% of children with sarcoidosis. In addition, ACE values may be difficult to interpret because reference values for serum ACE are age dependent. Fluorodeoxyglucose F18 positron emission tomography can help identify nonpulmonary sites for a diagnostic biopsy.

DIAGNOSIS

Definitive diagnosis ultimately requires demonstration of the characteristic noncaseating granulomatous lesions in a biopsy specimen (usually taken from the most readily available affected organ) and exclusion of other known causes of granulomatous inflammation. Skin and transbronchial lung biopsies have higher yield, greater specificity, and fewer associated adverse events than biopsy of mediastinal lymph nodes or liver. Additional diagnostic testing should include chest radiography, pulmonary function testing with measurement of diffusion capacity, hepatic enzyme measurements, and renal function assessment. Ophthalmologic slit-lamp examination is essential, as ocular findings are frequent in sarcoidosis and vision loss is a sequela of untreated disease.

Bronchoalveolar lavage may be used to assess for disease activity, and the fluid typically reveals an excess of lymphocytes with an increased CD4+/CD8+ ratio of 2:13:1. In addition to flexible bronchoscopy with transbronchial biopsy, endosonographic guided intrathoracic node aspiration has been valuable in obtaining tissue to assess for noncaseating granulomas.

DIFFERENTIAL DIAGNOSIS

Because of its protean manifestations, the differential diagnosis of sarcoidosis is extremely broad and depends largely on the initial clinical manifestations. Granulomatous infections, including tuberculosis, cryptococcosis, pulmonary mycoses (histoplasmosis, blastomycosis, coccidioidomycosis), brucellosis, tularemia, and toxoplasmosis, must be excluded. Other causes of granulomatous inflammation are
granulomatosis with polyangiitis (formerly Wegener granulomatosis), hypersensitivity pneumonia, chronic berylliosis, and other occupational exposures to metals. Immunodeficiencies that may manifest with granulomatous lesions include common variable immunodeficiency, selective immunoglobulin A deficiency, chronic granulomatous disease, ataxia telangiectasia, and severe combined immunodeficiency. Granulomas of the lung, skin or lymph nodes have been reported in patients treated with anti-TNF agents. Lymphoma should be ruled out in cases of hilar or other lymphadenopathy. Sarcoid arthritis may mimic juvenile idiopathic arthritis. Evaluation for endocrine disorders is needed in the setting of hypercalcemia or hypercalciuria.

TREATMENT
Treatment should be based on disease severity as well as the number and type of organs involved. Corticosteroids are the mainstay of treatment for most acute and chronic disease manifestations. The optimal dose and duration of corticosteroid therapy in children have not been established. Induction treatment typically begins with oral prednisone or prednisolone (1-2 mg/kg/day up to 40 mg daily) for 8-12 wk until manifestations improve. Corticosteroid dosage is then gradually decreased over 6-12 mo to the minimal effective maintenance dose (e.g., 5-10 mg/day) that controls symptoms, or discontinued if symptoms resolve. Methotrexate or leflunomide may be effective as a corticosteroid-sparing agent. On the basis of the role of TNF-α in the formation of granulomas, there is rationale for use of TNF-α antagonists. Results of small clinical trials showed modest effects with infliximab and adalimumab treatment of selected disease manifestations (CNS, lupus pernio, pulmonary, ocular), whereas etanercept does not appear to be particularly effective. Other therapeutics used for sarcoidosis manifestations include topical corticosteroids (eye), inhaled corticosteroids (lung), azathioprine (CNS), cyclophosphamide (cardiac, CNS), hydroxychloroquine (skin), mycophenolate mofetil (CNS, skin), thalidomide or its analogs (skin), and nonsteroidal antiinflammatory drugs (joints).

With regard to treatment of EOS, there are also few case reports on the successful use of thalidomide and infliximab. Findings of elevated IL-1 levels and response to human IL-1 receptor antagonist (anakinra) in EOS, however, have been inconsistent.

PROGNOSIS
The prognosis of childhood sarcoidosis is not well defined. The disease may be self-limited with complete recovery or may persist with a progressive or relapsing course. Outcome is worse in the setting of multi-organ or CNS involvement. Most children requiring treatment experience considerable improvement with corticosteroids, though a significant number have morbid sequelae, mainly involving the lungs and eyes. Children with EOS have a poorer prognosis and generally experience a more chronic, progressive disease course. The greatest morbidity is associated with ocular involvement, including cataract formation, development of synechiae, and loss of visual acuity or blindness; long-term systemic treatment may be required for the eye disease. Progressive polyarthritis may result in joint destruction. The overall mortality rate in childhood sarcoidosis is low.

Serial pulmonary function tests and chest radiographs are useful in following the course of lung involvement. Monitoring for other organ involvement should also include electrocardiogram with consideration of an echocardiogram, urinalysis, renal function tests, and measurements of hepatic enzymes and serum calcium. Other potential indicators of disease activity include inflammatory markers and serum ACE, although changes in ACE level do not always correlate with other indicators of disease status. Given the frequency of asymptomatic eye disease and the ocular morbidity associated with pediatric sarcoidosis, all patients should have an ophthalmologic examination at presentation with monitoring at regular intervals, perhaps every 3-6 mo as recommended in children with juvenile idiopathic arthritis.

Bibliography is available at Expert Consult.
Bibliography

Kawasaki disease (KD), formerly known as mucocutaneous lymph node syndrome and infantile polyarteritis nodosa, is an acute febrile illness of childhood seen worldwide with the highest incidence occurring in Asian children. KD is a vasculitis with a predilection for the coronary arteries. Approximately 20-25% of untreated children develop coronary artery abnormalities (CAA) including aneurysms, whereas <5% of children treated with intravenous gammaglobulin (IVIG) develop CAA. Nonetheless, KD is the leading cause of acquired heart disease in children in most developed countries, including the United States and Japan.

ETIOLOGY
The cause of KD remains unknown, but certain epidemiologic and clinical features support an infectious origin. These features include the young age group affected, epidemics with wave-like geographic spread of illness, the self-limited nature of the acute febrile illness, and the clinical features of fever, rash, enanthem, conjunctival injection, and cervical lymphadenopathy. Further evidence of an infectious trigger includes the infrequent occurrence of the illness in infants younger than 3 mo, likely the result of maternal antibodies, and the rarity of cases in adults, likely the result of prior exposures with subsequent immunity. However, there are features that are not consistent with an infectious origin. For example, it is unusual to have multiple cases present at the same time within a family or daycare center. Furthermore, no single infectious etiologic agent has been successfully identified, despite a comprehensive search.

A genetic role in the pathogenesis of KD seems likely, as evidenced by the higher risk of KD in Asian children regardless of country of residence, and in siblings and children of individuals with a history of KD. Furthermore, linkage studies and genome-wide association studies have identified significant associations between polymorphisms in the ITPKC gene, a T-cell regulator, with increased susceptibility to KD and to more-severe disease. Polymorphisms in a high-affinity receptor for immunoglobulin G (FCGR2A) have also been identified as significant variants in KD patients.

EPIDEMIOLOGY
For the majority of patients, KD is a disease of early childhood and nearly all epidemiologic studies show a higher susceptibility to KD in boys. Utilizing the Kids Inpatient Database to study trends in KD hospitalizations in 2006, Holman et al reported that more than 75% of all KD-associated hospitalizations in patients <18 yr were recorded in children <5 yr, with a mean age of 3 yr. Children of Asian and Pacific Islander descent had the highest hospitalization rate of 30.3/100,000 children, compared with 17.5/100,000 black, non-Hispanic children, 15.7/100,000 Hispanic children, and 12/100,000 white, non-Hispanic children. The hospitalization rate for KD in 2006 was 20.8/100,000 in children <5 yr of age, which was consistent with the prior 10 yr of hospitalization rates in the United States. In other countries, such as the United Kingdom, Korea, and Japan, the rate of KD seems to be increasing.

In Japan, nationwide surveys have been administered every 2 yr to monitor trends in KD incidence. In 2010, the highest recorded rate thus far of 239.6 per 100,000 children ages 0–4 yr was described, with the highest rate in very young children ages 6–11 mo. Infants <6 mo and children >5 yr were at the highest risk for CAA in the latest Japanese survey.

Several risk stratification models have been constructed to determine which patients with KD are at highest risk for CAA. Predictors of poor outcome across several studies include young age, male gender,
persistent fever, poor response to IVIG, and laboratory abnormalities including neutrophilia, thrombocytopenia, transaminis, hyponatremia, hypoalbuminemia, elevated levels of N-terminal-probrain natriuretic protein and elevated C-reactive protein levels. Asian and Pacific Islander race and Hispanic ethnicity are also risk factors for CAA. Three specific risk scores have been constructed by Japanese researchers; of these, the Kobayashi score is the most widely used and has high sensitivity and specificity. Unfortunately, application of these risk scores in non-Japanese populations does not appear to accurately identify all children at risk for IVIG resistance and CAA.

PATHOLOGY
KD is a vasculitis that predominantly affects the medium-size arteries. The coronary arteries are the most commonly involved, although other arteries, such as the popliteal and brachial arteries, can also develop dilation. A 3-phase process to the arteriopathy of KD has been described. The 1st phase is a neutrophilic necrotizing arteritis occurring in the 1st 2 wk of illness that begins in the endothelium and moves through the coronary wall. Saccular aneurysms may form from this arteritis. The second phase is a subacute/chronic vasculitis driven by lymphocytes, plasma cells, and eosinophils, which may last weeks to years and results in fusiform aneurysms. The vessels affected by the subacute/chronic vasculitis then develop smooth muscle cell myofibroblasts, which cause progressive stenosis. Thrombi may form in the lumen and obstruct blood flow.

CLINICAL MANIFESTATIONS
Fever is characteristically high (>38.3°C [101°F]), unremitting, and unresponsive to antibiotics. The duration of fever without treatment is generally 1-2 wk, but may persist for 3-4 wk. In addition to fever, the 5 principal clinical criteria of KD are: bilateral nonexudative conjunctival injection with limbal sparing; erythema of the oral and pharyngeal mucosa with strawberry tongue and red, cracked lips; edema and erythema of the hands and feet; rash of various forms (maculopapular, erythema multiforme, or scarlatiniform); and nonsuppurative cervical lymphadenopathy, usually unilateral, with node size >1.5 cm (Table 166-1; Figs. 166-1 to 166-4). Perineal desquamation is common in the acute phase. Periungual desquamation of the fingers and toes begins 2-3 wk after the onset of illness and may progress to involve the entire hand and foot (Fig. 166-5).

Symptoms other than the clinical criteria are common in the 10 days prior to diagnosis of KD, which may be explained in part by the finding that up to a third of patients with KD have confirmed, concurrent infections. Gastrointestinal symptoms (vomiting, diarrhea, or abdominal pain) occur in more than 60% of patients, and at least 1 respiratory symptom (rhinorrhea or cough) occurs in 35%. Other clinical findings include significant irritability that is especially prominent in infants and likely a consequence of aseptic meningitis, mild hepatitis, edema, and thrombocytopenia with sterile pyuria, and arthritis. Arthritis may occur early in the illness or may develop in the 2nd or 3rd wk. Small or large joints may be affected, and the arthralgias

*Table 166-1 Clinical and Laboratory Features of Kawasaki Disease

#### EPIDEMIOLOGIC CASE DEFINITION
(CLASSIC CLINICAL CRITERIA)*
- Fever persisting at least 5 days
- Presence of at least 4 principal features:
  - Changes in extremities: Acute: Erythema of palms, soles; edema of hands, feet
  - Subacute: Erythema of palms, soles; edema of hands, feet
  - Periungual peeling of fingers, toes in weeks 2 and 3
  - Palmar/planar skin rash
  - BCG, reactivation of bacille Calmette-Guérin inoculation site
  - Bilateral bulbar conjunctival injection without exudate
  - Changes in lips and oral cavity: erythema, lip cracking, strawberry tongue, diffuse injection of oral and pharyngeal mucosa
  - Cervical lymphadenopathy (>1.5 cm diameter), usually unilateral
  - Perineal desquamation
  - Enlarged lymph nodes, usually unilateral
  - Other findings: Erythema, induration at bacille Calmette-Guérin inoculation site
  - Extravascular coagulation
  - Aseptic meningitis
  - Sensorineural hearing loss
  - Genitourinary system: Urinary retention
  - Erythrocyte sedimentation rate
  - Leukocyte count
  - C-reactive protein
  - Erythrocyte sedimentation rate
  - Leukocyte count
  - C-reactive protein
  - Erythrocyte sedimentation rate
  - Leukocyte count
  - C-reactive protein
  - Erythrocyte sedimentation rate

#### OTHER CLINICAL AND LABORATORY FINDINGS

- Cardiovascular findings:
  - Congestive heart failure, myocarditis, pericarditis, valvular regurgitation
  - Coronary artery abnormalities
  - Aneurysms of medium-size noncoronary arteries
  - Raynaud phenomenon
  - Peripheral gangrene
  - Musculoskeletal system:
    - Arthritis, arthralgias
  - Gastrointestinal tract:
    - Diarrhea, vomiting, abdominal pain
  - Hepatic dysfunction
  - Hydrops of gallbladder
  - Central nervous system:
    - Extreme irritability
    - Aseptic meningitis
    - Sensorineural hearing loss
  - Genitourinary system:
    - Urinary retention
- Other findings:
  - Erythema, induration at bacille Calmette-Guérin inoculation site
  - Anterior uveitis (mild)
  - Desquamating rash in groin

#### LABORATORY FINDINGS IN ACUTE KAWASAKI DISEASE

- Leukocytosis with neutrophilia and immature forms
- Elevated erythrocyte sedimentation rate
- Elevated C-reactive protein
  - Anemia
  - Abnormal plasma lipids
  - Hypoalbuminemia
  - Hyponatremia
  - Thrombocytosis after week 1
- Sterile pyuria
  - Elevated serum transaminases
  - Elevated serum gamma glutamyl transpeptidase
  - Pleocytosis of cerebrospinal fluid
  - Leukocytosis in synovial fluid

*Patients with fever at least 5 days and <4 principal criteria can be diagnosed with Kawasaki disease when coronary artery abnormalities are detected by 2-dimensional echocardiography or angiography.

1In the presence of 24 principal criteria, Kawasaki disease diagnosis can be made on day 4 of illness. Experienced clinicians who have treated many patients with Kawasaki disease may establish diagnosis before day 4.

2Some differential diagnosis (Table 166-2).

---

**Figure 166-1 Clinical symptoms and signs of Kawasaki disease.** A summary of the clinical features from 110 cases of Kawasaki disease seen in Kaohsiung, Taiwan. LAP, lymphadenopathy in head and neck area; BCG, reactivation of bacille Calmette-Guérin inoculation site; CAD, coronary artery dilation, defined by an internal diameter >3 mm. (From Wang CL, Wu YT, Liu CA, et al: Kawasaki disease: infection, immunity and genetics, Pediatr Infect Dis J 24:998–1004, 2005.)
may persist for several weeks. Clinical features that are less consistent with KD include exudative conjunctivitis, exudative pharyngitis, generalized lymphadenopathy, discrete oral lesions, and bullous, pustular, or vesicular rashes.

Cardiac involvement is the most important manifestation of KD. Myocarditis occurs in most patients with acute KD and manifests as tachycardia disproportionate to fever, along with diminished left ventricular systolic function. Occasionally, patients with KD present in cardiogenic shock (KD shock syndrome), with markedly diminished left ventricular function. Pericarditis with a small pericardial effusion can also occur during the acute illness. Mitral regurgitation of at least mild severity is evident on echocardiography in 10-25% of patients at presentation but diminishes over time, except among rare patients with coronary aneurysms and ischemic heart disease. CAA develop in up to 25% of untreated patients in the 2nd to 3rd wk of illness. Giant coronary artery aneurysms (classic definition of >8 mm internal diameter) pose the greatest risk for rupture, thrombosis or stenosis, and myocardial infarction (Fig. 166-6). Axillary, popliteal, iliac, or other arteries may also become dilated, which manifest as a localized pulsating mass.

Occasionally KD initially presents with only fever and lymphadenopathy (node-first KD). This presentation may be confused with
bacterial or viral cervical lymphadenopathy/lymphadenitis and may delay the diagnosis of KD. Persistence of high fever, unresponsive to antibiotics and the eventual development of other signs of KD result in the diagnosis. Children with node-first KD tend to be older (4 vs. 2 yr) and have more days of fever and higher C-reactive protein levels. In addition to cervical adenopathy, many had retropharyngeal and peritonsillar inflammation on CT scans (Fig. 166-7).

KD can be divided into 3 clinical phases. The acute febrile phase is characterized by fever and the other acute signs of illness and usually lasts 1-2 wk. The subacute phase is associated with desquamation, thrombocytosis, the development of CAA, the highest risk of sudden death in patients in whom aneurysms have developed, and generally lasts about 3 wk. The convalescent phase begins when all clinical signs of illness have disappeared and continues until the erythrocyte sedimentation rate (ESR) returns to normal, typically about 6-8 wk after the onset of illness.

LABORATORY AND RADIOLOGY FINDINGS

There is no diagnostic test for KD, but patients usually have characteristic laboratory findings. The leukocyte count is often elevated, with a predominance of neutrophils and immature forms. Normocytic, normochromic anemia is common. The platelet count is generally normal in the 1st wk of illness and rapidly increases by the 2nd to 3rd wk of illness, sometimes exceeding 1,000,000/mm³. An elevated ESR and/or C-reactive protein value is universally present in the acute phase of illness. The ESR may remain elevated for weeks, in part from the effect of IVIG. Sterile pyuria, mild elevations of the hepatic transaminases, hyperbilirubinemia, and cerebrospinal fluid pleocytosis may also be present.

Two-dimensional echocardiography is the most useful test to monitor for development of CAA and should be performed by a pediatric cardiologist. Although frank aneurysms are rarely detected early in the illness, lack of normal tapering of the vessels is typical. Moreover, coronary artery dimensions, adjusted for body surface area, may be increased in the 1st 5 wk after presentation. Body surface area–adjusted coronary artery dimensions on baseline echocardiography in the 1st 10 days of illness appear to be good predictors of involvement during early follow-up. However, children with non-KD febrile illnesses also have mildly increased z scores as compared to nonfebrile controls, but not to the same degree as patients with KD. Aneurysms have been defined with use of absolute dimensions by the Japanese Ministry of Health and are classified as small (<5 mm internal diameter), medium (5-8 mm internal diameter), or giant (>8 mm internal diameter). Some experts believe that a z-score–based system for classification of aneurysm size may be more discriminating given the range in sizes of patients with KD. Under such a system, a z score ≥10 is considered giant and hence defines the threshold at which anticoagulation should be initiated.

Echocardiography should be performed at diagnosis and again after 2-3 wk of illness. If the results are normal, a repeat study should be performed 6-8 wk after onset of illness. If results of either of the initial studies are abnormal or the patient has recurrent fever or symptoms, more frequent echocardiography or other studies may be necessary. In patients without coronary abnormalities at any time during the illness, performance of echocardiography and a lipid profile is recommended 1 year later. After this time, periodic evaluation for preventive cardiology counseling is warranted, and some experts recommend cardiologic follow-up every 5 yr. For patients with coronary abnormalities, the type of testing and the frequency of cardiology follow-up visits are tailored to the patients’ coronary status.

DIAGNOSIS

The diagnosis of KD is based on the presence of characteristic clinical signs. For classic KD, the diagnostic criteria require the presence of fever for at least 4 days and at least 4 of 5 of the other principal characteristics of the illness (see Table 166-1). In atypical or incomplete KD, patients have persistent fever but fewer than 4 of the 5 characteristics. In these patients, laboratory and echocardiographic data can assist in the diagnosis (Fig. 166-8). Incomplete cases are most frequent in infants, who, unfortunately, also have the highest likelihood of development of CAA. Ambiguous cases should be referred to a center with experience in the diagnosis of KD. Establishing the diagnosis with prompt institution of treatment is essential to prevent potentially devastating coronary artery disease.

DIFFERENTIAL DIAGNOSIS

Adenovirus, measles, and scarlet fever lead the list of common childhood infections that mimic KD (Table 166-2). Children with adenovirus typically have exudative pharyngitis and exudative conjunctivitis, allowing differentiation from KD. A common clinical problem is the differentiation of scarlet fever from KD in a child who is a group A streptococcal carrier. Patients with scarlet fever typically have a rapid clinical response to appropriate antibiotic therapy. Such treatment for 24-48 hr with clinical reassessment generally clarifies the diagnosis. Furthermore, ocular findings are quite rare in group A streptococcal pharyngitis and may assist in the diagnosis of KD.

Features of measles that distinguish it from KD include exudative conjunctivitis, Koplik spots, rash that begins on the face and hairline and behind the ears, as well as leukopenia. Cervical lymphadenitis can

Figure 166-8 Algorithm for evaluation of suspected incomplete Kawasaki disease (KD). (1) In the absence of a gold standard for diagnosis, this algorithm cannot be evidence based, but rather represents the informed opinion of the expert committee. Consultation with an expert should be sought anytime assistance is needed. (2) Infants ≤6 mo old on day ≥7 of fever or later without other explanation should undergo laboratory testing and, if evidence of systemic inflammation is found, given an echocardiogram (Echo), even if they have no clinical criteria. (3) Patient characteristics suggesting KD are listed in Table 166-1. Characteristics suggesting disease other than KD include exudative conjunctivitis, exudative pharyngitis, and, if evidence of systemic inflammation is found, given an echocardiogram (Echo), even if they have no clinical criteria. (4) Supplemental laboratory criteria include albumin ≤3.0 g/dL, anemia for age, elevation of alanine aminotransferase, platelet count after 7 days ≥450,000/mm³, white blood cell count ≥15,000/mm³, and urine white blood cell count ≥10/high-power field. (5) Can treat before performing echocardiogram. (6) Echocardiogram findings are considered positive (Echo+) for purposes of this algorithm if any of 3 conditions are met: z score of left anterior descending coronary artery (LAD) or right coronary artery (RCA) ≥2.5; coronary arteries meet Japanese Ministry of Health criteria for aneurysms; ≥3 other suggestive features exist, including perivascular brightness, lack of tapering, decreased left ventricle (LV) function, mitral regurgitation, pericardial effusion, or z scores in LAD or RCA of 2-2.5. (7) If echocardiogram findings are positive, treatment should be given to children within 10 days of fever onset and to those beyond day 10 with clinical and laboratory signs (C-reactive protein [CRP], erythrocyte sedimentation rate [ESR]) of ongoing inflammation. (8) Typical peeling begins under nail beds of fingers and then toes. Echo−, negative echocardiogram findings; f/u, follow-up. (From Newburger JW, Takahashi M, Gerber MA, et al: Diagnosis, treatment, and long-term management of Kawasaki disease, Pediatrics 114:1708–1733, 2004.)

be the initial diagnosis in children who are ultimately recognized to have KD. Less common infections such as Rocky Mountain spotted fever and leptospirosis are occasionally confused with KD. Rocky Mountain spotted fever is a potentially lethal bacterial infection and appropriate antibiotics should not be withheld if the diagnosis is considered. Its distinguishing features include pronounced myalgias and headache at onset, centripedal rash, and petechiae on the palms and soles. Leptospirosis can also be an illness of considerable severity. Risk factors include exposure to water contaminated with urine from infected animals. The classic description of leptospirosis is of a biphasic illness with a few asymptomatic days between an initial period of fever and headache and a late phase with renal and hepatic failure. In contrast, patients with KD have consecutive days of fever at diagnosis and rarely have renal or hepatic failure.

Children with KD and pronounced myocarditis may demonstrate hypotension with a clinical picture similar to that of toxic shock syndrome. Features of toxic shock syndrome that are not commonly seen in KD include renal insufficiency, coagulopathy, pancytopenia, and myositis. Drug hypersensitivity reactions, including Stevens-Johnson syndrome, share some characteristics with KD. Drug reaction features such as the presence of periorbital edema, oral ulcers, and a normal or minimally elevated ESR are not seen in KD. Systemic-onset juvenile idiopathic arthritis is also characterized by fever and rash, but physical findings include diffuse lymphadenopathy and hepatosplenomegaly. Arthritis is required to develop at some point in the disease course to make the diagnosis, but may not be present in the 1st few wk of illness. Laboratory findings may include coagulopathy, elevated fibrin degradation product values, and hyperferritinemia. Interestingly, there are reports of children with systemic-onset juvenile idiopathic arthritis who have echocardiographic evidence of abnormal coronary arteries. Coronary aneurysms have also been reported in Behçet disease, primary cytomegalovirus infection, and meningococcemia.

TREATMENT
Patients with acute KD should be treated with 2 g/kg of IVIG and high-dose aspirin (80-100 mg/kg/day divided q6h) within 10 days of disease onset and ideally as soon as possible after diagnosis (Table 166-3). The

</table>

**COMPLICATIONS**

The patient with KD who has had a small solitary aneurysm should continue aspirin indefinitely. Patients with larger or numerous aneurysms may require the addition of other antiplatelet agents or anticoagulation; such decisions should be made in consultation with a pediatric cardiologist. Acute thrombosis may occasionally occur in an aneurysmal or stenotic coronary artery; thrombolytic therapy may be lifesaving in this circumstance.

Long-term follow-up of patients with coronary artery aneurysms should include periodic echocardiography with stress testing and possibly angiography if large aneurysms are present. Catheter intervention with percutaneous transluminal coronary rotational ablation, directional coronary athrectomy, and stent implantation have been used for the management of coronary stenosis due to KD, with some patients requiring coronary artery bypass grafting. Patients undergoing long-term aspirin therapy should receive annual influenza vaccination to reduce the risk of Reye syndrome. A different antiplatelet agent can be substituted for aspirin during the 6 wk after varicella vaccination. As IVIG may interfere with the immune response to live virus vaccines as a result of specific antiviral antibody, the measles-mumps-rubella and varicella vaccinations should generally be deferred until 11 mo after IVIG administration. Non-live vaccinations do not need to be delayed.

**PROGNOSIS**

The vast majority of patients with KD return to normal health, as timely treatment reduces the risk of coronary aneurysms to less than 5%. Acute KD recurs in 1-3% of cases. The prognosis for patients with coronary abnormalities depends on the severity of coronary disease; therefore, recommendations for follow-up and management are stratified according to coronary artery status. Published mortality rates are very low, generally <1.0%. Overall, 50% of coronary artery aneurysms regress to normal lumen diameter by 1-2 yr after the illness, with smaller aneurysms being more likely to regress. Intravascular ultrasonography has demonstrated that regressed aneurysms are associated with marked myointimal thickening and abnormal functional behavior of the vessel wall. Giant aneurysms are less likely to regress to normal lumen diameter and are most likely to lead to thrombosis or stenosis. Coronary artery bypass grafting may be required if myocardial perfusion is significantly impaired; it is best accomplished with the use of arterial grafts, which grow with the child and are more likely than venous grafts to remain patent over the long-term. Heart transplantation has been required in rare cases in which revascularization is not feasible because of distal coronary stenoses, distal aneurysms, or severe ischemic cardiomyopathy. A study from Japan reported outcomes in adult patients with a history of KD and giant aneurysms. These patients required multiple cardiac and surgical procedures, but the 30-year survival rate approached 90%.

Whether children who have had KD and normal echocardiography findings throughout their course are at higher risk for the development of atherosclerotic heart disease in adulthood remains unclear, as studies of endothelial dysfunction in children with a history of KD and normal coronary dimensions have produced conflicting results. Reassuring data suggest that the standardized mortality ratio among adults in Japan who had KD in childhood without aneurysms is indistinguishable from that of the general population. All children with a history of KD should be counseled regarding a heart-healthy diet, adequate amounts of exercise, tobacco avoidance, and intermittent lipid monitoring. Among children with coronary aneurysms, the American Heart Association recommends treatment thresholds for risk factors for atherosclerotic heart disease that are lower than those for the normal population.

* Bibliography is available at Expert Consult.*
Bibliography

Childhood vasculitis encompasses a broad spectrum of diseases that share in common inflammation of the blood vessels as the central pathophysiology. The pathogenesis of the vasculitides is generally idiopathic; some forms of vasculitis are associated with infectious agents and medications; others may occur in the setting of preexisting autoimmune disease. The pattern of vascular injury provides insight into the form of vasculitis and serves as a framework to delineate the different vasculitic syndromes. The distribution of vascular injury includes small vessels (capillaries, arterioles, and postcapillary venules), medium vessels (renal arteries, mesenteric vasculature, and coronary arteries), and large vessels (the aorta and its proximal branches). Additionally, some forms of small vessel vasculitis are characterized by the presence of antineutrophil cytoplasmic antibodies (ANCAs) (Table 167-1), whereas others are associated with immune complex deposition in affected tissues. A combination of clinical features, histologic appearance of involved vessels, and laboratory data is utilized to classify vasculitis (Tables 167-2 to 167-4).

Childhood vasculitis varies from a relatively benign and self-limited disease such as Henoch-Schönlein purpura to catastrophic disease with end-organ damage as can be seen in granulomatosis with polyangiitis (formerly Wegener granulomatosis). Vasculitis generally manifests as a heterogeneous multisystem disease. Although some features, such as purpura, are easily identifiable, others, such as hypertension secondary to renal artery occlusion or glomerulonephritis, can be more subtle. Ultimately, the key to recognizing vasculitis relies heavily on pattern recognition. Demonstration of vessel injury and inflammation on biopsy or vascular imaging is required to confirm a diagnosis of vasculitis.

- Fever, weight loss, fatigue of unknown origin
- Skin lesions (palpable purpura, vasculitic urticaria, livedo reticularis, nodules, ulcers)
- Neurologic lesions (headache, mononeuritis multiplex, focal central nervous system lesions)
- Arthritis or arthralgia, myalgia, or myositis
- Serositis
- Hypertension
- Pulmonary infiltrates or hemorrhage

**LABORATORY FEATURES**
- Increased erythrocytes sedimentation rate or C-reactive protein level
- Leukocytosis, anemia
- Eosinophilia
- Antineutrophil cytoplasmic antibodies
- Elevated factor VIII-related antigen (von Willebrand factor)
- Cryoglobulins
- Circulating immune complexes
- Hematuria, proteinuria, elevated serum creatinine

---

ANCA, Antibodies directed at neutrophil cytoplasmic antigen; BPI, Bactericidal permeability increasing protein. cANCA, cytoplasmic ANCA; pANCA, perinuclear ANCA.

**Bibliography**

HSP occasionally clusters in families, suggesting a genetic component. That HSP is a disease mediated by IgA and IgA immune complexes. The common finding of deposition of IgA, specifically IgA1, suggests Staphylococcus aureus, infectious triggers such as group A β-hemolytic streptococcus, Staphylococcus aureus, mycoplasma, and adenovirus have been suspected. The common finding of deposition of IgA, specifically IgA1, suggests that HSP is a disease mediated by IgA and IgA immune complexes. HSP occasionally clusters in families, suggesting a genetic component.

167.1 Henoch-Schönlein Purpura

Stacy P. Ardoin and Edward Fels

Henoch-Schönlein purpura (HSP) is the most common vasculitis of childhood and is characterized by leukocytoclastic vasculitis and immunoglobulin (Ig) A deposition in the small vessels in the skin, joints, gastrointestinal tract, and kidney.

**EPIDEMIOLOGY**

HSP occurs worldwide and affects all ethnic groups but is more common in white and Asian populations. The incidence of HSP is estimated at 1.2-1.8/100,000 children per year and affects males more than females, with a 1.2-1.8:1 male:femail ratio. Approximately 90% of HSP cases occur in children, usually between the ages of 3 and 10 yr. HSP is distinctly less common in adults, in whom severe and chronic complications are often encountered. HSP is more common in the winter and spring, and is unusual in summer months. Many cases of HSP follow a documented upper respiratory infection.

**PATHOLOGY**

Skin biopsies demonstrate vasculitis of the dermal capillaries and post-capillary venules. The inflammatory infiltrate includes neutrophils and monocytes. Renal histopathology typically shows endocapillary proliferative glomerulonephritis, ranging from a focal segmental process to extensive crescentic involvement. In all tissues, immunofluorescence identifies IgA deposition in walls of small vessels (Fig. 167-1), accompanied to a lesser extent by deposition of C3, fibrin, and IgM.

**PATHOGENESIS**

The exact pathogenesis of HSP remains unknown. Given the seasonality of HSP and the frequency of preceding upper respiratory infections, infectious triggers such as group A γ-hemolytic streptococcus, Staphylococcus aureus, mycoplasma, and adenovirus have been suspected. The common finding of deposition of IgA, specifically IgA1, suggests that HSP is a disease mediated by IgA and IgA immune complexes. HSP occasionally clusters in families, suggesting a genetic component.

HLA-B34 and HLA-DRB1*01 alleles have been linked to HSP nephritis. Patients with familial Mediterranean fever, hereditary periodic fever syndromes, and complement deficiencies are at increased risk for developing HSP, suggesting that genetically determined immune dysregulation may contribute.

**CLINICAL MANIFESTATIONS**

The hallmark of HSP is its rash: palpable purpura starting as pink macules or wheals and developing into petechiae, raised purpura, or larger ecchymoses. Occasionally, bullae and ulcerations develop. The skin lesions are usually symmetric and occur in gravity-dependent areas (lower extremities) or on pressure points (buttocks) (see Figs. 167-1 and 167-2). The skin lesions evolve in groups, typically lasting 3–10 days, and may recur up to 4 mo after initial presentation. Subcutaneous edema localized to the dorsa of hands and feet, periarticular area, lips, scrotum, or scalp is also common.

Musculoskeletal involvement, including arthritis and arthralgias, is common, occurring in up to 75% of children with HSP. The arthritis tends to be self-limited and oligoarticular, with a predilection for the lower extremities, and does not lead to deformities. The arthritis usually resolves within 2 wk but can recur.

Gastrointestinal manifestations of HSP occur in up to 80% of children with HSP and include abdominal pain, vomiting, diarrhea, paralytic ileus and melela; intussusception, mesenteric ischemia, intestinal perforation are uncommon. Endoscopic evaluation is usually not needed but may identify purpura of the intestinal tract.

Renal involvement occurs in up to 50% of children with HSP, manifesting as microscopic hematuria, proteinuria, hypertension, frank nephritis, nephrotic syndrome, and acute or chronic renal failure. Progression to end-stage renal disease is uncommon in children (1–2%) (see Chapter 515).

Neurologic manifestations of HSP, caused by hypertension or central nervous system (CNS) vasculitis, may also occur. They include intracerebral hemorrhage, seizures, headaches, and behavior changes. Other less-common potential manifestations of HSP are orchitis, carditis, inflammatory eye disease, testicular torsion, and pulmonary hemorrhage.

Chapter 167 ◆ Vasculitis Syndromes

**DIAGNOSIS**

The diagnosis of HSP is a clinical one and is often straightforward when the typical rash is present. However, in at least 25% of cases, the rash appears after other manifestations, making early diagnosis challenging. Table 167-5 summarizes the classification criteria for HSP. The differential diagnosis for HSP depends on specific organ involvement but usually includes other small vessel vasculitides, infections, acute post streptococcal glomerulonephritis, hemolytic-uremic syndrome, coagulopathies, and other acute intraabdominal processes.

**Acute hemorrhagic edema (AHE),** an isolated cutaneous leukocytoclastic vasculitis that affects infants <2 yr of age, resembles HSP clinically. AHE manifests as fever; tender edema of the face, scrotum, hands, and feet; and ecchymosis (usually larger than the purpura of HSP) on the face and extremities (Fig. 167-3). The trunk is spared, but petechiae may be seen in mucous membranes. The patient usually appears well except for the rash. The platelet count is normal or elevated, and the urinalysis results are normal. The younger age, the nature of the lesions, absence of other organ involvement, and a biopsy may help distinguish AHE from HSP.

**Papular-purpuric gloves-and-socks syndrome** is most commonly caused by parvovirus B19 and initially manifests with symmetric edema and erythema over the hands and feet. These well-demarcated lesions end at the ankle and wrist and evolve into purpuric papules. Fever, oral lesions, and leukopenia are inconsistent findings. Complications include mononeuritis multiplex. Adolescents are more often affected than young children. In contrast to erythema infectiosum, patients with papular-purpuric gloves-and-socks syndrome are usually infectious at the time of appearance of the rash.

**LABORATORY FINDINGS**

No laboratory finding is diagnostic of HSP. Common but nonspecific findings include leukocytosis, thrombocytosis, mild anemia, and elevations of erythrocyte sedimentation rate (ESR) and C-reactive protein.
involvement with blood pressure, urinalysis, and serum creatinine is necessary.

Ultrasound is often used in the setting of gastrointestinal complaints to look for bowel wall edema or the rare occurrence of an associated intussusception. Barium enema can also be used to both diagnose and treat intussusception. Although often unnecessary in typical HSP, biopsies of skin and kidney can provide important diagnostic information, particularly in atypical or severe cases, and characteristically show IgA deposition in affected tissues.

**TREATMENT**

Treatment for mild and self-limited HSP is supportive, with an emphasis on assuring adequate hydration, nutrition, and analgesia. Steroids are most often used to treat significant gastrointestinal involvement or other life-threatening manifestations. Prednisone (1 mg/kg/day for 1-2 wk, followed by taper) reduces abdominal and joint pain but does not alter overall prognosis nor prevent renal disease. Rapid tapering of corticosteroids may lead to a flare of HSP symptoms. Although few data are available to demonstrate efficacy, intravenous immune globulin and plasma exchange are sometimes used in the setting of severe disease. In some cases, chronic HSP renal disease is managed with a variety of immunosuppressants, including azathioprine, cyclophosphamide, cyclosporine, and mycophenolate mofetil. End-stage renal disease develops in up to 8% of children with HSP nephritis.

**COMPLICATIONS**

Acutely, serious gastrointestinal involvement such as intestinal perforation imparts significant morbidity and mortality. Renal disease is the major long-term complication, occurring in 1-2% of children with HSP. Renal disease can develop up to 6 mo after diagnosis but rarely does so if the initial urinalyses findings are normal. It is recommended that children with HSP undergo serial monitoring of blood pressure and urinalyses for several months after diagnosis to monitor for the development of nephritis.

**PROGNOSIS**

Overall, the prognosis for childhood HSP is excellent, and most children experience an acute, self-limited course lasting on average 4 wk. From 15-60% of children with HSP experience 1 or more recurrences, typically within 4-6 mo of diagnosis. With each relapse, symptoms are usually milder than at presentation. Children with a more-severe initial course are at higher risk for relapse. The long-term prognosis usually depends upon the severity and duration of gastrointestinal or renal involvement. Chronic renal disease develops in 1-2% of children with HSP, and approximately 8% of those with HSP nephritis go on to have end-stage renal disease. The risk of HSP recurrence and graft loss following renal transplantation is estimated at 7.5% after 10 yr.

include fibromuscular dysplasia, Marfan syndrome, and Ehlers-Danlos syndrome.

LABORATORY FINDINGS

The laboratory findings in TA are nonspecific, and there is no specific diagnostic laboratory test. ESR and CRP value are typically elevated, and other nonspecific markers of chronic inflammation may include leukocytosis, thrombocytosis, anemia of chronic inflammation, and hypergammaglobulinemia. Autoantibodies are not useful in diagnosing TA except to help exclude other autoimmune diseases.

Radiographic assessment is essential to establish large vessel arterial involvement. Conventional arteriography of the aorta and major branches, including carotid, subclavian, pulmonary, renal, and mesenteric branches can identify luminal defects, including dilation, aneurysms, and stenoses, even in smaller vessels such as the mesenteric arteries. Figure 167-4 shows a conventional arteriogram in a child with TA. Although not yet thoroughly validated in TA, magnetic resonance angiography and CT angiography also provide important information about vessel wall thickness and enhancement, although they may not image smaller vessels as well as conventional angiography. Positron emission tomography may detect vessel wall inflammation but has not been studied extensively. Ultrasound with duplex color-flow Doppler imaging also identifies vessel wall thickening and assesses arterial flow. Echocardiography is recommended to assess for aortic valvular involvement. Serial vascular imaging is usually necessary to assess response to treatment and to detect progressive vascular damage.

TREATMENT

Glucocorticoids are the mainstay of therapy, typically starting with high doses (1-2 mg/kg/day of prednisone) followed by gradual dosage tapering. When TA progresses or recurs, steroid-sparing therapy is often required, usually involving methotrexate or azathioprine. Cyclophosphamide is reserved for severe or refractory disease. Results of small case series also suggest that mycophenolate mofetil, tocilizumab or anti–TNF-α therapy may be beneficial in select patients. Antiinflammatory medications are often necessary to control blood pressure caused by renovascular disease.

COMPLICATIONS

Progressive vascular damage can result in arterial stenoses, aneurysms, and occlusions, which produce ischemic symptoms and can be organ- or life-threatening. Potential ischemic complications include stroke, renal impairment or failure, myocardial infarction, mesenteric ischemia, and limb-threatening arterial disease. When these complications occur or are imminent, intervention with surgical vascular grafting or catheter-based angioplasty and stent placement may be necessary to restore adequate blood flow. A high rate of recurrent stenosis has been reported following angioplasty and stent placement. Aortic valve replacement may be required if significant aortic insufficiency develops.
Polyarteritis nodosa (PAN) is a systemic necrotizing vasculitis affecting small and medium-size arteries. Aneurysms and stenoses form at irregular intervals throughout affected arteries. Cutaneous PAN is limited to the skin.

**Epidemiology**

PAN is rare in childhood. Boys and girls are equally affected, and the mean age at presentation is 9 yr. The cause is unknown, but the development of PAN following infections, including group A streptococcus and chronic hepatitis B, suggests that PAN may represent a postinfectious autoimmune response. Infections with other organisms, including Epstein-Barr virus, *Mycobacterium tuberculosis*, cytomegalovirus, parvovirus B19, and hepatitis C virus, have also been associated with PAN. As in Henoch-Schönlein purpura, there is a possible association between PAN and familial Mediterranean fever.

**Pathology**

Biopsies show necrotizing vasculitis with granulocytes and monocytes infiltrating the walls of small and medium-size arteries (Fig. 167-5). Involvement is usually segmental and tends to occur at vessel bifurcations. Granulomatous inflammation is not present, and deposition of complement and immune complexes is rarely observed. Different stages of inflammation are found, ranging from mild inflammatory changes to panmural fibrinoid necrosis associated with aneurysm formation, thrombosis, and vascular occlusion.

**Pathogenesis**

Immune complexes are believed to be pathogenic, but the mechanism is poorly understood. There is no clear genetic association with PAN, and it is not known why PAN has a predilection for small- and medium-size blood vessels. The inflamed vessel wall becomes thickened and narrowed, impeding blood flow and contributing to end-organ damage characteristic of this disease. Familial disease in Georgian Jewish patients has been reported to be due to mutations in the *CECR1* gene, which encodes adenosine deaminase 2.

**Clinical Manifestations**

The clinical presentation of PAN is variable but generally reflects the distribution of inflamed vessels. Constitutional symptoms are present in most children at disease onset. Weight loss and severe abdominal pain suggest mesenteric arterial inflammation and ischemia. Renovascular arteritis can cause hypertension, hematuria, or proteinuria, although glomerulonephritis is not typical. Cutaneous manifestations include purpura, livedo reticularis, ulcerations, digital ischemia and painful nodules. Arteritis affecting the nervous system can result in cerebrovascular accidents, transient ischemic attacks, psychosis, and ischemic motor or sensory peripheral neuropathy (mononeuritis multiplex). Myocarditis or coronary arteritis can lead to heart failure and myocardial ischemia; pericarditis and arrhythmias have also been reported. Arthralgias, arthritis, or myalgias are frequently present. Less common symptoms include testicular pain that mimics testicular torsion, bone pain, and vision loss as a result of retinal arteritis. The pulmonary vasculature is usually spared in PAN.

**Diagnosis**

The diagnosis of PAN requires demonstration of vessel involvement on biopsy or angiography (Table 167-7). Biopsy of cutaneous lesions is available at Expert Consult.

*The presence of all 5 criteria provides 89.6% sensitivity and 99.6% specificity for the diagnosis of childhood onset polyarteritis nodosa.*

shows small or medium vessel vasculitis (see Fig. 167-5). Kidney biopsy in patients with renal manifestations may show necrotizing arteritis. Electromyography in children with peripheral neuropathy identifies affected nerves, and sural nerve biopsy may reveal vasculitis. Conventional arteriography is the gold standard diagnostic imaging study for PAN and reveals areas of aneurysmal dilation and segmental stenosis, the classic “beads on a string” appearance (Fig. 167-6). Magnetic resonance angiography and CT angiography, less-invasive imaging alternatives, are gaining acceptance, but may not be as effective in identifying small vessel disease or in younger children.

**DIFFERENTIAL DIAGNOSIS**

Early skin lesions may resemble those of HSP, although the finding of nodular lesions and presence of systemic features help distinguish PAN. Because pulmonary vascular involvement is very rare in PAN, pulmonary lesions suggest ANCA-associated vasculitis or Goodpasture disease. Other rheumatic diseases, including systemic lupus erythematosus, have characteristic target organ involvement and associated autoantibodies distinguishing them from PAN. Prolonged fever and weight loss should also prompt consideration of inflammatory bowel disease or malignancy.

**LABORATORY FINDINGS**

Nonspecific laboratory findings include elevations of ESR and CRP, anemia, leukocytosis, and hypergammaglobulinemia. Abnormal urine sediment, proteinuria, and hematuria indicate renal disease. Laboratory findings may be normal in cutaneous PAN or similar to those of systemic PAN. Elevated hepatic enzyme values may suggest hepatitis B or C infection. Serologic tests for hepatitis (hepatitis B surface antigen and hepatitis C antibody) should be performed in all patients.

**TREATMENT**

Oral (1-2 mg/kg/day) and intravenous pulse (30 mg/kg/day) prednisone is the mainstay of therapy. Oral or intravenous cyclophosphamide are often used as adjunctive therapy, and plasma exchange may be warranted for life-threatening disease. If hepatitis B is identified, appropriate antiviral therapy should be initiated (see Chapter 358).

Most cases of cutaneous PAN can be treated with less-intense therapy such as corticosteroids alone, nonsteroidal antiinflammatory agents, and methotrexate. Azathioprine, mycophenolate mofetil, intravenous immunoglobulin, cyclosporine, and anti-TNF have all been reported as successful in treatment of refractory cutaneous or systemic PAN, although clinical trials are lacking. If an infectious trigger for PAN is identified, antibiotic prophylaxis can be considered.

**COMPICATIONS**

Cutaneous nodules may ulcerate and become infected. Hypertension and chronic renal disease may develop from renovascular involvement in PAN. Cardiac involvement may lead to decreased cardiac function or coronary artery disease. Mesenteric vasculitis can predispose to bowel infarction, rupture, and malabsorption. Stroke and rupture of hepatic arterial aneurysm are uncommon complications of this disorder.

**PROGNOSIS**

The course of PAN varies from mild disease with few complications to a severe, multiorgan disease with high morbidity and mortality. Poor prognostic factors in PAN include elevated serum creatinine, proteinuria, severe gastrointestinal involvement, cardiomyopathy, and CNS involvement. Early and aggressive immunosuppressive therapy increases the likelihood of clinical remission. Compared with disease in adults, childhood PAN is associated with less mortality. Cutaneous PAN is unlikely to transition to systemic disease. Early recognition and treatment of the disease are important to minimizing potential long-term vascular complications.

*Bibliography is available at Expert Consult.*

### 167.4 Antineutrophilic Cytoplasmic Antibody–Associated Vasculitis

Stacy P. Ardoin and Edward Fels

The ANCA-associated vasculitides are characterized by small vessel involvement, circulating ANCAAs, and pauci-immune complex deposition in affected tissues. ANCA-associated vasculitis is categorized into 3 distinct forms: granulomatosis with polyangiitis (GPA; formerly...
Bibliography
Wegener granulomatosis, microscopic polyangiitis (MPA), and eosinophilic granulomatosis with polyangiitis, formerly called Churg-Strauss syndrome (CSS) (see Table 167-1).

**EPIDEMIOLOGY**
GPA is a necrotizing granulomatous small and medium vessel vasculitis that occurs at all ages and targets the upper and lower respiratory tracts and the kidneys. Although most cases of GPA occur in adults, the disease also occurs in children with a mean age at diagnosis of 14 yr. There is a female predominance of 3-4:1, and pediatric GPA is most prevalent in whites.

MPA is a small vessel necrotizing vasculitis with clinical features similar to those of GPA. CSS is a small vessel necrotizing granulomatous (allergic granulomatosis) vasculitis associated with a history of refractory asthma and peripheral eosinophilia. MPA and CSS are rare in children, and there does not appear to be a gender predilection in either disease.

**PATHOLOGY**
Necrotizing vasculitis is the cardinal histologic feature in both GPA and MPA. Kidney biopsies typically demonstrate crescentic glomerulonephritis with little or no immune complex deposition (“pauci-immune”), in contrast to biopsies from patients with systemic lupus erythematosus. Although granulomatous inflammation is common in GPA and CSS, it is typically not present in MPA. Biopsies showing perivascular eosinophilic infiltrates distinguish CSS syndrome from both MPA and GPA (see Table 167-7).

**PATHOGENESIS**
The etiology of ANCA-associated vasculitis remains unknown, although neutrophils, monocytes, and endothelial cells are involved in disease pathogenesis. Neutrophils and monocytes are activated by ANCs, specifically by the ANCA-associated antigens proteinase-3 (PR3) and myeloperoxidase (MPO), and release proinflammatory cytokines such as TNF-α and IL-8. Localization of these inflammatory cells to the endothelium results in vascular damage characteristic of the ANCA vasculitides. Why the respiratory tract and kidneys are preferential targets in GPA and MPA is unknown.

**CLINICAL MANIFESTATIONS**
Early disease course is characterized by nonspecific constitutional symptoms, including fever, malaise, weight loss, myalgias, and arthralgias. In GPA, upper airway involvement can manifest as sinusitis, nasal ulceration, epistaxis, otitis media, and hearing loss. Lower respiratory tract symptoms in GPA include cough, wheezing, dyspnea, and hemoptysis. Pulmonary hemorrhage can cause rapid respiratory failure. Compared with adults, childhood GPA is more frequently complicated by subglottic stenosis (see Fig. 167-5). Inflammation-induced damage to the nasal cartilage can produce a saddle nose deformity (Fig. 167-7). Ophthalmic involvement includes conjunctivitis, scleritis, uveitis, optic neuritis, and invasive orbital pseudotumor (causing proptosis). Perineural vasculitis or direct compression on nerves by granulomatous lesions can cause cranial and peripheral neuropathies. Hematuria, proteinuria, and hypertension in GPA signal renal disease. Cutaneous lesions can cause cranial and peripheral neuropathies. Hematuria, proteinuria, and hypertension in GPA signal renal disease. Cutaneous lesions include palpable purpura and ulcers. Venous thromboembolism is a rare but potentially fatal complication of GPA. The frequencies of organ system involvement throughout the disease course in GPA are: respiratory tract, 84%; kidneys, 88%; joints, 44%; eyes, 60%; skin, 48%; sinuses, 56%; and nervous system, 12%. Table 167-8 outlines the classification criteria for pediatric-onset GPA.

The clinical presentation of MPA closely resembles that of GPA, although sinus disease is less common; systemic features of fever, malaise, weight loss, myalgias, arthralgias may be dominant. MPA predominantly affects the kidney and lungs; other organ systems include skin, CNS, muscle, heart, and eyes. CSS frequently causes inflammation of the upper and lower respiratory tracts, but cartilage destruction is rare. CSS may initially demonstrate chronic or recurrent rhinitis/sinusitis, nasal polyposis, and difficult to treat asthma. Eosinophilia with pulmonary infiltrates may precede a vasculitic phase. Other organ involvement includes skin, cardiac, peripheral nerves, gastrointestinal tract, and muscle. Renal involvement in CSS is uncommon.

**DIAGNOSIS**
GPA should be considered in children who have recalcitrant sinusitis, pulmonary infiltrates, and evidence of nephritis. Chest radiography often fails to detect pulmonary lesions, and chest CT may show nodules, ground-glass opacities, mediastinal lymphadenopathy, and cavitary lesions (Fig. 167-8). The diagnosis is confirmed by the presence of anti-PR3–specific ANCs (PR3-ANCAs) and the finding of necrotizing granulomatous vasculitis on pulmonary, sinus, or renal biopsy. The ANCA test result is positive in approximately 90% of children with GPA, and the presence of anti-PR3 increases the specificity of the test.

In MPA, ANCs are also frequently present but have reactivity to MPO (MPO-ANCAs). MPA can be distinguished from PAN by the...
presence of ANCAAs and the tendency for small vessel involvement. The 
ANCA test result is positive in approximately 70% of cases of CSS, and
MPO-ANCAs are more common than PR3-ANCAs. The presence
of chronic asthma and peripheral eosinophilia suggests the diagnosis
of CSS.

### DIFFERENTIAL DIAGNOSIS
ANCAs are absent in other granulomatous diseases, such as sarcoidosis
and tuberculosis. Goodpasture disease is characterized by antibodies
to glomerular basement membrane. Medications such as propylthio-
uracil, hydralazine, and minocycline are associated with drug-induced
ANCA (usually perinuclear ANCA) vasculitis. Systemic lupus ery-
thematosus and HSP can manifest as pulmonary hemorrhage and
nephritis.

### LABORATORY FINDINGS
Elevated ESR and CRP values, leukocytosis, and thrombocytosis are
present in most patients with an ANCA-associated vasculitis but are
nonspecific. Anemia may be caused by chronic inflammation or pul-
monary hemorrhage. ANCA antibodies show 2 distinct immunofluor-
escence patterns: perinuclear and cytoplasmic. In addition, ANCAAs
can also be defined by their specificity for PR3 or MPO antigen. GPA
is strongly associated with cytoplasmic ANCAAs/anti-PR3 antibodies
(see Tables 167-1 and 167-9).

### TREATMENT
When the lower respiratory tract or kidneys are significantly involved,
initial induction therapy usually consists of corticosteroids (2 mg/kg/
day oral or 30 mg/kg/day × 3 days given intravenously) in conjunction
with daily oral cyclophosphamide (2 mg/kg/day). Rituximab is an
option for induction therapy in ANCA positive vasculitides although

*Signs and symptoms of small vessel vasculitis include purpura, other rash, arthralgias, arthritis, and constitutional symptoms.

---

has been studied primarily in adults. Patients are transitioned to a less toxic maintenance medication (usually methotrexate, azathioprine, or mycophenolate mofetil) within 3-6 mo once remission is achieved. Trimethoprim-sulfamethoxazole (one 180 mg/800 mg tablet 3 days/wk) is often prescribed both for prophylaxis against *Pneumocystis jiroveci* infection and to reduce upper respiratory bacterial colonization with *S. aureus*, which may trigger disease activity. If disease is limited to the upper respiratory tract, corticosteroids (1-2 mg/kg/day) and methotrexate (0.5-1.0 mg/kg/wk) may be first-line treatment.

**COMPILATIONS**

Upper respiratory tract lesions can invade the orbit and threaten the optic nerve, and lesions in the ear can cause permanent hearing loss. Respiratory complications include potentially life-threatening pulmonary hemorrhage and upper airway obstruction due to subglottic stenosis. Chronic lung disease secondary to granulomatous inflammation, cavitary lesions, and scarring can predispose to infectious complications. Chronic glomerulonephritis may progress to end-stage renal disease in a subset of patients with advanced or undertreated disease.

**PROGNOSIS**

The course is variable but disease relapse occurs in up to 60% of patients. Mortality has been reduced with the introduction of cyclo-

#### 167.5 Other Vasculitis Syndromes

*Stacy P. Ardoin and Edward Fels*

In addition to the more common vasculitides discussed earlier in this chapter, other vasculitic conditions can occur in childhood, the most common of which is Kawasaki disease (see Chapter 166). Hypersensitivity vasculitis is a cutaneous vasculitis triggered by medication or toxin exposure. The rash consists of palpable purpura or other nonspecific rash. Skin biopsies reveal characteristic changes of leukocytoclastic vasculitis (small vessels with neutrophilic perivascular or extravascular neutrophilic infiltration). Hypocomplementemic urticarial vasculitis involves small vessels and manifests as recurrent urticaria that resolves over several days but leaves residual hyperpigmentation. This condition is associated with low levels of complement component C1q and systemic findings that include fever, gastrointestinal symptoms, arthritis, and glomerulonephritis. Cryoglobulinemic vasculitis can complicate mixed essential cryoglobulinemia and is a small vessel vasculitis affecting skin, joints, kidneys, and lungs.

Primary angiitis of the CNS represents vasculitis confined to the CNS and requires exclusion of other systemic vasculitides. Large vessel disease (angiography positive) may manifest with focal deficits similar to an occlusive stroke with hemiparesis, focal gross or fine motor deficits, language disorders, or cranial nerve deficits. Diffuse cognitive, memory, and concentration deficits plus behavioral disorders are seen in 30-40%. Small vessel (angiography negative, biopsy positive) involvement more often demonstrates language problems and diffuse deficits such as cognitive, memory, behavior, and concentration problems as well as focal seizures.

Benign angitis of the CNS, also known as transient CNS angiopathy, represents a self-limited variant. Cogan syndrome is rare in children; its potential clinical manifestations include constitutional symptoms, inflammatory eye disease, vestibuloaditory dysfunction, arthritis, and aortitis.

Identification of these vasculitis syndromes requires a comprehensive history and physical exam. Table 167-10 outlines other diagnostic considerations. Although treatment is tailored to disease severity, treatment generally includes prednisone (up to 2 mg/kg/day) plus steroid-sparing immunosuppressive medications if necessary. For hypersensitivity vasculitis, withdrawal of the triggering medication or toxin is indicated if possible.

### Bibliography is available at Expert Consult.
Bibliography
Bibliography

Musculoskeletal pain is a frequent complaint of children presenting to general pediatricians and is the most common presenting problem of children referred to pediatric rheumatology clinics. Prevalence estimates of persistent musculoskeletal pain in community samples range from roughly 10-30%. Although diseases such as juvenile idiopathic arthritis and systemic lupus erythematosus may manifest as persistent musculoskeletal pain, the majority of musculoskeletal pain complaints in children turn out to be benign in nature and attributable to trauma, overuse, and normal skeletal growth variations. There is a subset of children in whom chronic pain complaints develop in the absence of physical and laboratory abnormalities. Children with idiopathic musculoskeletal pain syndromes, also typically develop marked subjective distress and functional impairment. Therefore, the treatment of children with musculoskeletal pain syndromes optimally includes both pharmacologic and nonpharmacologic interventions.

**CLINICAL MANIFESTATIONS**

Chronic musculoskeletal pain syndromes involve pain complaints of at least 3 mo in duration in the absence of objective abnormalities on physical examination and laboratory screening. Additionally, children and adolescents with musculoskeletal pain syndromes often complain...
of persistent pain despite previous treatment with nonsteroidal anti-inflammator drugs and analgesic agents. The location varies, with pain complaints either localized to a single extremity or more diffuse and involving multiple extremities. It is not uncommon for the pain to start in a single area of the body before intensifying and radiating to other areas over time. The prevalence of musculoskeletal pain syndromes increases with age and is higher in females, thus rendering adolescent girls at highest risk.

The somatic complaints of children and adolescents with musculoskeletal pain syndromes are commonly accompanied by psychological distress, sleep difficulties, and functional impairment across home, school, and peer domains. Psychological distress may include symptoms of anxiety and depression, such as frequent crying spells, fatigue, sleep disturbance, feelings of worthlessness, poor concentration, and frequent worry. Indeed, a substantial number of children with musculoskeletal pain syndromes display the full range of psychological symptoms warranting an additional diagnosis of a comorbid mood or anxiety disorder (e.g., major depressive episode, generalized anxiety disorder). Sleep disturbance in children with musculoskeletal pain syndromes may include difficulty falling asleep, multiple night awakenings, disrupted sleep-wake cycles with increased daytime sleeping, nonrestorative sleep, and fatigue.

For children and adolescents with musculoskeletal pain syndromes, the constellation of pain, psychological distress, and sleep disturbance often leads to a high degree of functional impairment. Poor school attendance is common, and children may struggle to complete other daily activities relating to self-care and participation in household chores. Decreased physical fitness can also occur, as well as changes in gait and posture, as children avoid contact with or use of the body area affected by pain. Peer relationships may also be disrupted due to decreased opportunities for social interaction due to pain. As such, children and adolescents with musculoskeletal pain syndromes often report loneliness and social isolation characterized by having few friends and lack of participation in extracurricular activities.

**DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS**

The diagnosis of a musculoskeletal pain syndrome is typically one of exclusion when careful, repeated physical examinations and laboratory testing do not reveal an etiology. At initial presentation, children with pain complaints require a thorough clinical history and a complete physical examination to look for an obvious etiology (e.g., sprains, strains, or fractures), characteristics of the pain (localized or diffuse), and evidence of systemic involvement. A comprehensive history can be particularly useful in providing clues to the possibility of underlying illness or systemic disease. The presence of current or recent fever can be indicative of an inflammatory or neoplastic process if the pain is also accompanied by worsening symptoms over time or weight loss.

Subsequent, repeated physical examinations of children with musculoskeletal pain complaints may reveal eventual development and manifestations of rheumatic or other diseases. The need for additional testing should be individualized, depending on the specific symptoms and physical findings. Laboratory screening and/or radiographs should be pursued if there is suspicion of certain underlying disease processes. Possible indicators of a serious, as opposed to a benign, cause of musculoskeletal pain include pain present at rest and relieved by activity, objective joint swelling on physical examination, stiffness or limited range of motion in joints, bony tenderness, muscle weakness, poor growth and/or weight loss, and constitutional symptoms (e.g., fever, malaise) (Table 168-1). In the case of laboratory screenings, a complete blood count and erythrocyte sedimentation rate are likely to be abnormal in children whose pain is secondary to a bone or joint infection, systemic lupus erythematosus, or a malignancy. Bone tumors, fractures, and other focal pathology resulting from infection, malignancy, or trauma can often be identified through imaging studies, including plain film x-rays, MRI, and technetium-99m bone scans.

The presence of persistent pain, accompanied by psychological distress, sleep disturbance, and/or functional impairment, in the absence of objective laboratory or physical examination abnormalities, suggest the diagnosis of a musculoskeletal pain syndrome. All pediatric musculoskeletal pain syndromes share this general constellation of symptoms at presentation. Several more specific pain syndromes routinely seen by pediatric practitioners can be differentiated by anatomic region and associated symptoms. Pediatric musculoskeletal pain syndromes are listed in Table 168-2 and includes growing pains (see Chapter 168.1), fibromyalgia (see Chapter 168.3), complex regional pain syndrome (see Chapter 168.4), localized pain syndromes, low back pain, and chronic sports-related pain syndromes (e.g., Osgood-Schlatter disease).

**TREATMENT**

The primary goal of treatment for pediatric musculoskeletal pain syndromes is to improve function rather than relieve pain, and these two desirable outcomes may not occur simultaneously. Indeed, it is common for children with musculoskeletal pain syndromes to continue complaining of pain even as they resume normal function (e.g., increased school attendance and participation in extracurricular activities). For all children and adolescents with pediatric musculoskeletal pain syndromes, regular school attendance is crucial, as this is a hallmark of normal functioning in this age group. The dual nature of treatment, targeting both function and pain, needs to be clearly

explained to children and their families to better outline the goals by which treatment success will be measured. Indeed, children and families need to be supported in disengaging from the sole pursuit of pain relief and embracing broader treatment goals of improved functioning.

Recommended treatment modalities typically include physical and/or occupational therapy, pharmacologic interventions, and cognitive-behavioral and/or other psychotherapeutic interventions. The overarching goal of physical therapy is to improve children’s physical function and should emphasize participation in aggressive, but graduated aerobic exercise. Pharmacologic interventions should be used judiciously. Low-dose tricyclic antidepressants (amitriptyline 10-50 mg orally 30 min before bedtime) are indicated for treatment of sleep disturbance; selective serotonin reuptake inhibitors (sertraline 10-20 mg daily) may prove useful in treating symptoms of depression and anxiety if present. Referral for psychological evaluation is warranted if these symptoms do not resolve with initial treatment efforts or if suicidal ideation is present. Cognitive-behavioral and/or other psychotherapeutic interventions are typically designed to teach children and adolescents coping skills for controlling the behavioral, cognitive, and physiologic responses to pain. Specific components often include cognitive restructuring, relaxation, distraction, and problem-solving skills; additional targets of therapy include sleep hygiene and activity scheduling, all with the goal of restoring normal sleep patterns and activities of daily living. Parent education and involvement in the psychological intervention is important to ensure maintenance of progress. More intensive family-based approaches are warranted if barriers to treatment success are identified at the family level. These could include parenting strategies or family dynamics that serve to maintain children’s pain complaints, such as overly solicitous responses to child pain, and maladaptive models for pain coping in the family.

**COMPLICATIONS AND PROGNOSIS**

Musculoskeletal pain syndromes can negatively affect child development and future role functioning. Worsening pain and the associated symptoms of depression and anxiety can lead to substantial school absences, peer isolation, and developmental delays later in adolescence and early adulthood. Specifically, adolescents with musculoskeletal pain syndromes may fail to achieve the level of autonomy and independence necessary for age-appropriate activities such as attending college, living away from home, and maintaining a job. Fortunately, not all children and adolescents with musculoskeletal pain syndromes experience this degree of impairment and the likelihood of positive health outcomes is increased with multidisciplinary treatment.

**168.1 Growing Pains**

*Kelly K. Anthony and Laura E. Schanberg*

More appropriately termed **benign nocturnal pains of childhood** growing pains affect 10-20% of children, with a peak age incidence between 4 and 12 yr. Pain does not occur during periods of rapid growth or at growth sites. The most common cause of recurrent musculoskeletal pain in children, growing pains are intermittent and bilateral, predominantly affecting the anterior thigh, shin, and calf but not joints. Occasionally there may be unilateral upper extremity pain associated with leg pain; isolated upper extremity pain does not occur. Children most commonly describe cramping or aching that occurs in the late afternoon or evening. Pain may wake the child from sleep and may last a few minutes to hours, but resolves quickly with massage or analgesics; pain is never present the following morning (Table 168-3). Pain often follows a day with exercise or other physical activities. Physical findings are normal, and gait is not impaired. Growing pains are generally considered a benign, time-limited condition; there is evidence suggesting that growing pains represent a pain amplification syndrome. Indeed, growing pains persist in a significant percentage of children, with some children developing other pain syndromes such as abdominal pain and headaches. Growing pains are more likely to persist in children with a parent who has a history of a pain syndrome and in children who have lower pain thresholds. Treatment should also focus on reassurance, education, and healthy sleep hygiene. Massage
during the episode is very effective, and nonsteroidal antiinflammatory drugs agents may be useful for frequent episodes.

Restless leg syndrome, seen more commonly among adults, is a sensorimotor disturbance that may be confused with growing pains (see Chapter 19). Restless leg syndrome is a difficult to control urge to move the leg that is exacerbated during rest and at night and is relieved by movement.

### 168.2 Small Fiber Polyneuropathy

**Kelly K. Anthony and Laura E. Schanberg**

Many patients with juvenile onset widespread pain syndromes, as well as patients with pediatric fibromyalgia (see Chapter 168.3), complex regional pain syndrome type I (see Chapter 168.4), and erythromelalgia have evidence of a small fiber polyneuropathy causing dysfunctional or degeneration of small diameter unmyelinated C-fibers and thinly myelinated A-delta fibers that mediate nociception and the autonomic nervous system. Fibromyalgia (see Chapter 168.3) includes chronic widespread pain defined as ≥3 mo duration of axial pain that is often bilateral and also affects the upper and lower extremities. In addition, many patients have associated chronic cardiovascular (dizziness, postural orthostasis syndrome) symptoms, as well as chronic abdominal pain and ileus, headaches, fatigue and erythromelalgia, suggestive of dysautonomia.

There are no typical findings on physical exam or standard laboratory tests. The diagnosis of small fiber polyneuropathy requires distal leg skin immunolabeled biopsy to identify epidermal nociceptive fibers and autonomic function testing to examine cardiovascular, adrenergic, and sudomotor small fiber function.

Treatment of patients with small fiber polyneuropathy and isolated juvenile-onset widespread pain syndrome, or those subsets of patients with small fiber polyneuropathy and fibromyalgia, complex regional pain syndrome, or erythromelalgia is evolving and has included prednisone or intravenous immunoglobulin.

**Bibliography is available at Expert Consult.**

### 168.3 Fibromyalgia

**Kelly K. Anthony and Laura E. Schanberg**

Juvenile primary fibromyalgia syndrome (JFPS) is a common pediatric musculoskeletal pain syndrome. Approximately 25-40% of children with chronic pain syndromes can be diagnosed with JFPS. Although specific diagnostic criteria for JFPS have not been determined, children and adolescents with JFPS have diffuse, multifocal, waxing and waning, and at times migratory musculoskeletal pain in at least 3 areas of the body that persists for at least 3 mo in the absence of an underlying condition. Results of laboratory tests are normal, and physical examination reveals at least 5 well-defined tender points (Fig. 168-1). Children and adolescents with JFPS also present with many associated symptoms, including nonrestorative sleep, fatigue, paresthesias, chronic anxiety or tension, chronic headaches, subjective soft-tissue swelling, and pain modulated by physical activity, weather, and anxiety or stress. There is considerable overlap among symptoms associated with JFPS and complaints associated with other functional disorders (e.g., irritable bowel disease, migraines, temporomandibular joint disorder, premenstrual syndrome, mood and anxiety disorders, and chronic fatigue syndrome), raising speculation that these disorders may be part of a larger spectrum of related syndromes.

Although the precise cause of JFPS is unknown, there is an emerging understanding that the development and maintenance of JFPS are related both to biologic and psychological factors. JFPS is an abnormality of central pain processing characterized by disordered sleep physiology, enhanced pain perception with abnormal levels of substance P in cerebrospinal fluid, disordered mood, and dysregulation of hypothalamic–pituitary–adrenal and other neuroendocrine axes resulting in lower tender-point pain thresholds and increased pain sensitivity. Children and adolescents with fibromyalgia often find themselves in a vicious cycle of pain, whereby symptoms build upon one another and contribute to the onset and maintenance of new symptoms (Fig. 168-2).

JFPS has a chronic course that can detrimentally affect child health and development. Adolescents with JFPS who do not receive...
Bibliography

Complex regional pain syndrome (CRPS) is characterized by ongoing burning limb pain that is subsequent to an injury, immobilization, or another noxious event affecting the extremity. CRPS1, formerly called reflex sympathetic dystrophy, has no evidence of nerve injury, whereas CRPS2, formerly called causalgia, follows a prior nerve injury. Key associated features are pain disproportionate to the inciting event, persisting allodynia (a heightened pain response to normally non-noxious stimuli), hyperalgesia (exaggerated pain reactivity to noxious stimuli), swelling of distal extremities, and indicators of autonomic dysfunction (i.e., cyanosis, mottling, and hyperhidrosis) (Table 168-4).

The diagnosis requires the following: an initiating noxious event or immobilization; continued pain, allodynia, and hyperalgesia out of proportion to the inciting event; evidence of edema, skin blood flow abnormalities, or sudomotor activity; and exclusion of other disorders. Associated features include atrophy of hair or nails; altered hair growth; abnormalities, or sudomotor activity; and exclusion of other disorders. Associated features include atrophy of hair or nails; altered hair growth; abnormalities, or sudomotor activity; and exclusion of other disorders.

*A diagnosis of CRPS requires regional pain, sensory symptoms, plus 2 neuropathic pain descriptors and 2 physical signs of autonomic dysfunction.

**168.4 Complex Regional Pain Syndrome**

Kelly K. Anthony and Laura E. Schanberg

Complex regional pain syndrome (CRPS) is characterized by ongoing burning limb pain that is subsequent to an injury, immobilization, or another noxious event affecting the extremity. CRPS1, formerly called reflex sympathetic dystrophy, has no evidence of nerve injury, whereas CRPS2, formerly called causalgia, follows a prior nerve injury. Key associated features are pain disproportionate to the inciting event, persisting allodynia (a heightened pain response to normally non-noxious stimuli), hyperalgesia (exaggerated pain reactivity to noxious stimuli), swelling of distal extremities, and indicators of autonomic dysfunction (i.e., cyanosis, mottling, and hyperhidrosis) (Table 168-4).

The diagnosis requires the following: an initiating noxious event or immobilization; continued pain, allodynia, and hyperalgesia out of proportion to the inciting event; evidence of edema, skin blood flow abnormalities, or sudomotor activity; and exclusion of other disorders. Associated features include atrophy of hair or nails; altered hair growth; loss of joint mobility; weakness, tremor, dystonia; and sympathetically maintained pain.

Although the majority of pediatric patients with CRPS present with a history of minor trauma or repeated stress injury (e.g., caused by competitive sports), a sizeable proportion are unable to identify a precipitating event. Usual age of onset is between 8 and 16 yr, and girls outnumber boys with the disease by as much as 6:1. Childhood CRPS differs from the adult form in that lower extremities, rather than upper extremities, are most commonly affected. The incidence of CRPS in children is unknown, largely because it is often undiagnosed or diagnosed late, with the diagnosis frequently delayed by nearly a year. Left untreated, CRPS can have severe consequences for children including bone demineralization, muscle wasting, and joint contractures.

An evidence-based approach to the treatment of CRPS continues to suggest a multistage treatment approach. Aggressive physical therapy should be initiated as soon as the diagnosis is made and cognitive-behavioral interventions (CBT) added as needed. Physical therapy (PT) is recommended 3-4 times per week, and children may need analgesic premedication at the onset, particularly prior to PT sessions. PT is initially limited to desensitization and then moves to weight-bearing, range-of-motion, and other functional activities. CBT used as an adjunctive therapy targets psychosocial obstacles to fully participating in PT and provides pain coping skills training. Sympathetic and epidural nerve blocks should be attempted only under the auspices of a pediatric pain specialist. The intent of both pharmacologic and adjunctive treatments for CRPS is to provide sufficient pain relief to allow the child to participate in aggressive physical rehabilitation. If CRPS is identified and treated early, the majority of children and adolescents with the disease can be treated successfully with low-dose amitriptyline (10-50 mg orally 30 min prior to bedtime), aggressive PT, and CBT interventions. Opioids and anticonvulsants such as gabapentin can also be helpful. Notably, multiple studies have shown non-invasive treatments, particularly PT and CBT, are at least as efficacious as nerve blocks in helping children with CRPS achieve resolution of their symptoms.

There is growing evidence that some patients with CRPS I have a small fiber polyneuropathy (see Chapter 168.2).

**168.5 Erythromelalgia**

Laura E. Schanberg

Children with erythromelalgia experience episodes of intense pain, erythema, and heat in their hands and feet (Fig. 168-3). Less commonly involved are the face, ears, or knees. Symptoms may be triggered by exercise and exposure to heat, lasting for hours and occasionally for days. It is more common in girls and in the teenage years and diagnosis is often delayed for years. Although most cases are sporadic, an
Bibliography
Bibliography

autosomal dominant hereditary form results from mutations of the SCN9A gene on chromosome 2q31-32, causing a painful channelopathy. Secondary erythromelalgia is associated with an array of disorders, including myeloproliferative diseases, peripheral neuropathy, frostbite, hypertension, and rheumatic disease. Treatment includes avoidance of heat exposure as well as other precipitating situations and the utilization of cooling techniques that do not cause tissue damage during attacks. Nonsteroidal antiinflammatories, narcotics, anesthetic agents (lidocaine patch), anticonvulsants (oxcarbazepine, carbamazepine, gabapentin), and antidepressants, as well as biofeedback and hypnosis may be useful in helping manage pain. Drugs acting on the vascular system (aspirin, sodium nitroprusside, magnesium, misoprostol) may also be somewhat effective. However, a reliably efficacious treatment is not available, resulting in substantial negative impact on physical and mental health.

There is growing evidence that some patients with erythromelalgia have a small fiber polyneuropathy (see Chapter 168.2).

*Bibliography is available at Expert Consult.*
RELAPSING POLYCHONDРИTIS

Relapsing polychondritis (RP) is a rare condition characterized by episodic chondritis causing cartilage destruction and deformation of the ears (sparking the earlobes), nose, larynx and tracheobronchial tree. Antibodies to matrilin-1 and collagen (types II, IX and XI) are present in approximately 60% of patients with RP, suggesting an autoimmune pathogenesis. Patients may experience arthritis, uveitis, and hearing loss due to inflammation near the auditory and vestibular nerves. Children may initially relate episodes of intense erythema over the outer ears. Other dermatologic manifestations such as erythema nodosum, maculopapular rash and purpura may be seen. Cardiac involvement, including conduction defects and coronary vasculitis, has been reported. Severe, progressive, and potentially fatal disease resulting from destruction of the tracheobronchial tree and airway obstruction is unusual in childhood. Diagnostic criteria established for adults are useful guidelines for evaluating children with suggestive symptoms (Table 169-1). The clinical course of RP is variable; flares of disease are often associated with elevations of acute-phase reactants and may remit spontaneously. Although seen more commonly in the adult population, RP may coexist with other inflammatory diseases, such as systemic lupus erythematosus, Sjögren syndrome, and Henoch-Schönlein purpura. The differential diagnosis includes antineutrophilic cytoplasmic antibody–associated vasculitis (granulomatosis with polyangiitis) (see Chapter 167.4) and Cogan syndrome, which is characterized by auditory nerve inflammation and keratitis but not chondritis. Many children respond to nonsteroidal antiinflammatory drugs, but some require corticosteroids or other immunosuppressive agents (azathioprine, methotrexate, hydroxychloroquine, colchicine, cyclophosphamide, cyclosporine, and anti–tumor necrosis factor agents), as reported in small series and case reports.

MUCHA-HABERMANN DISEASE/PITYRIASIS LICHENOIDES ET VARIOLIFORMIS ACUTA

Pityriasis lichenoides et varioliformis acuta (PLEVA) is a benign, self-limited cutaneous vasculitis characterized by episodes of macules, papules, and papulovesicular lesions that can develop central ulceration, necrosis, and crusting. Different stages of development are usually seen at once. PLEVA fulminans or febrile ulceronecrotic Mucha-Habermann disease is the severe, life-threatening form of PLEVA. Large coalescing ulceronecrotic lesions are seen, and are accompanied by high fever and an elevated erythrocyte sedimentation rate. Systemic manifestations can include interstitial pneumonitis, abdominal pain, malabsorption, arthritis, and neurologic manifestations. There is a male predominance and it occurs more frequently in childhood. The diagnosis is confirmed by biopsy of skin lesions that reveal perivascular and intramural lymphocytic inflammation affecting capillaries and venules in the upper dermis that may lead to keratinocyte necrosis. When disease is severe, corticosteroids have been used with questionable effect, and methotrexate has been reported to induce rapid remission in resistant cases. Cyclosporine and anti–tumor necrosis factor agents have been efficacious in case reports.

SWEET SYNDROME

Sweet syndrome, or acute febrile neutrophilic dermatosis, is a rare entity in children. It is characterized by fever, elevated neutrophil count, and raised, tender erythematous plaques and nodules over the body.
Hypertrophic osteoarthropathy

Children with chronic disease, especially pulmonary or cardiac disease, can demonstrate clubbing of the terminal phalanges, and have associated periosteal reaction and arthritis. These findings characterize the classic presentation of hypertrophic osteoarthropathy (HOA). HOA can be primary (idiopathic), or secondary. Although rare, secondary HOA is more common in children, and is seen in children with chronic pulmonary disease (cystic fibrosis), congenital heart disease, gastrointestinal disease (malabsorption syndromes, biliary atresia, inflammatory bowel disease), and malignancies (nasopharyngeal sarcoma, osteosarcoma, Hodgkin disease). HOA may precede diagnosis of cardiopulmonary disease or malignancy. The pathogenesis of HOA is unknown; symptoms often improve if the underlying condition is treated successfully. HOA-related pain can be disabling, and in adults management with bisphosphonates has been reported. Evaluation of children presenting with HOA should include a chest radiograph to evaluate for pulmonary disease or intrathoracic mass.

Plant thorn synovitis

A diagnosis of plant thorn synovitis should be considered in children with monoarticular arthritis nonresponsive to antiinflammatory therapy. Acute or chronic arthritis can occur after a plant thorn or other foreign object penetrates a joint. Unlike septic arthritis, children with plant thorn synovitis are commonly afebrile. The most common organism seen with plant thorn synovitis is *Pantoea agglomerans*, although cultures are often negative. The initial injury may be unknown or forgotten, making diagnosis difficult. Ultrasound or magnetic resonance imaging can be useful in identifying the foreign body. Removal of the foreign body via arthroscopy followed by an antibiotic course is the accepted therapy.

Pigmented villonodular synovitis

Proliferation of synovial tissue is seen in pigmented villonodular synovitis (PVNS). This proliferation is either localized or diffuse, and can affect the joint, tendon sheath or bursa. Macrophages and multinucleated giant cells with brownish hemosiderin are present histologically. It is unclear if the etiology of PVNS is inflammatory or neoplastic in nature. Although findings are not pathognomonic, MRI with contrast is a useful diagnostic tool where PVNS can be seen as a mass or bone erosion. Brown or bloody synovial fluid is seen with arthrocentesis, but the diagnosis is made by tissue biopsy. Surgical removal of the affected tissue is the therapeutic modality, and with diffuse disease, a total synovectomy is recommended.

*The diagnosis is established by the presence of 2 major criteria plus 2 of the 4 minor criteria.

Bibliography

Laboratory evidence to support the diagnosis of an infectious disease may be based on 1 or more of the following: direct examination of specimens using microscopic or antigen detection techniques, isolation of microorganisms in culture, serologic testing, host gene expression patterns, and molecular detection of an organism, resistance determinant, or virulence factor. Additional important roles of the diagnostic microbiology lab are antimicrobial susceptibility testing to guide in the selection of the most appropriate antimicrobial therapy and supporting hospital infection prevention in the detection and characterization of pathogens associated with nosocomial infections.

**SPECIMEN COLLECTION**

The success of microbiology cultures, that is, isolation of a pathogen if present, is directly linked to specimen collection techniques. In general, this means collecting the correct specimen type for the disease or condition in question and promptly transporting the specimen to the laboratory for analysis. Although for some conditions swab specimens may be necessary, in general, a swab is a suboptimal specimen. A swab is only able to hold a very small amount of specimen. A swab is only able to hold a very small amount of specimen (approximately 100 μL), and using a traditional swab, only a small fraction of organisms that are absorbed onto a swab will be released back into the culture. Flocked swabs, coupled with transport medium, improve organism recovery. However, when possible, fluid or tissue should be submitted to the laboratory for analysis. If anaerobic infection is suspected, the sample should be transported in appropriate medium to preserve viability of anaerobic bacteria. For the recovery of some organism types, such as viruses and *Neisseria gonorrhoeae*, specific transport media may be required. Considerations specific to the collection of blood cultures will be addressed in the blood culture section.

**LABORATORY DIAGNOSIS OF BACTERIAL AND FUNGAL INFECTIONS**

Although the scope and availability of molecular methods for detection of bacterial and fungal pathogens is increasing at a rapid pace, the state-of-the-art for the diagnosis of many of these infections is dependent upon microscopic detection of organisms or cultivation of organisms on culture media.

**Microscopy**

The Gram stain is an extremely valuable diagnostic technique to provide rapid and inexpensive information regarding the absence or presence of inflammatory cells and organisms in clinical specimens. For some specimen types, the presence of inflammatory and epithelial cells is used to judge the suitability of a specimen for culture. For example, the presence of more than 10 epithelial cells per low-power field in a sputum specimen is highly suggestive of a specimen contaminated with oral secretions. In addition, a preliminary assessment of the etiologic agent can be made based upon the morphology (e.g., cocci vs rods) and stain reaction (e.g., Gram-positive isolates are purple; Gram-negative are red) of the microorganisms. However, a negative Gram stain does not rule out infection as 10¹ to 10¹² microorganisms per mL in the specimen are required for detection by this method.

In addition to the Gram stain, many other stains are used in microbiology, both to detect organisms and to help infer their identity. Table 170-1 provides an overview of the most commonly used stains.

**Isolation and Identification**

The approach to isolation of microorganisms in a clinical specimen will vary depending on the body site and pathogen suspected. For body sites that are usually sterile, such as cerebrospinal fluid, nutrient-rich media such as sheep blood agar and chocolate agar are used to aid in the recovery of fastidious pathogens. In contrast, stool specimens contain abundant amounts of commensal bacteria and thus to isolate pathogens, selective and differential media must be used. Selective media will inhibit the growth of some organisms to aid in isolation of suspect pathogens; differential media rely on growth characteristics or carbohydrate assimilation characteristics to impart a growth pattern that differentiates organisms. MacConkey agar supports growth of Gram-negative rods while suppressing Gram-positive organisms, and a color change in the media from clear to pink distinguishes lactose-fermenting organisms from other Gram-negative rods. Special media, such as Saboraud dextrose agar and inhibitory mold agar, are used to recover fungi in clinical specimens. Many pathogens, including *Bar- tonella*, *Bordetella pertussis*, *Legionella*, *Mycoplasma*, and certain fungal pathogens such as *Malassezia furfur*, require specialized growth media or incubation conditions. Consultation with the laboratory is advised when these pathogens are suspected.

Once an organism is recovered in culture, additional testing will be performed to identify the isolate. Confirmation of microbial identity has classically been performed using phenotypic tests that rely on the phenotypic properties of an isolate. Some examples include carbohydrate assimilation patterns, indole production, and motility. However, these methods are not able to resolve all organisms to species level and require incubation time. In some instances, sequence based identification, for bacteria usually based on sequence analysis of the bacterial 16S rRNA gene, is used for organism identification (particularly organisms that are difficult to culture).

Matrix-assisted laser desorption-ionization time-of-flight mass spectrometry (MALDI-TOF MS) is a rapid and accurate technique that is based on generating a protein fingerprint of an organism and comparing that fingerprint to a library of known organisms to produce an identification. This method can identify bacteria or yeast growing in culture in a matter of minutes, and the consumable costs for these analyses are minimal.

**Blood Culture**

The performance of blood cultures is one of the most important functions of the clinical microbiology laboratory. Most blood cultures are performed by collecting blood into bottles of nutrient-rich broth to facilitate the growth of bacteria and yeast. Some blood culture media contain resins or other agents to help neutralize antibiotics that may be present in the patients’ blood. Blood culture bottles are then incubated on an automated blood culture incubator that will monitor the blood culture bottle at regular intervals for evidence of growth. Once the instrument detects evidence of microbial growth, it will alarm to
alert the laboratory. Approximately 80% of blood cultures that will ultimately be positive are identified within the 1st 24 hr of incubation. A portion of broth from a blood culture bottle that has signaled positive is then Gram-stained and cultured onto appropriate growth media so that the organism can be isolated and identified. There are numerous pre-analytical variables that can influence the accuracy of blood culture results. In order to facilitate accurate interpretation of a positive blood culture, a minimum of 2 blood cultures drawn from different sites should be collected whenever possible. Growth of an organism that is part of the normal skin flora from a single blood culture raises concern that the isolate resulted from contamination of the culture. The volume of blood collected is also an important factor in the recovery of bloodstream pathogens, especially as the number of organisms per milliliter of blood in sepsis may be low. The optimal amount of blood to collect from a pediatric patient varies depending on the weight of the child. The Clinical and Laboratory Standards Institute and Cumitech documents provide guidance on the amount of blood to collect from children of different sizes. Paired collection of aerobic and anaerobic blood culture bottles will result in maximal recovery of pathogens if present.

There are a number of rapid diagnostic assays that can be used directly on positive blood culture broth to identify pathogens commonly associated with bacteremia and some antimicrobial resistance determinants. Most of these rapid diagnostic assays are based on nucleic acid detection techniques. An example of this is the Verigene system, which can identify a number of streptococcal and enterococcal species, as well as meca and vanA genes, in positive blood culture broth, in approximately 2 hr. MALDI-TOF MS can also be performed on blood culture broth that is positive for growth of microorganisms. These assays can help shorten the interval between a positive blood culture and definitive organism identification, with the goal of early optimization of antimicrobial therapy.

Detection of mycobacteria and some filamentous fungi (such as Histoplasma capsulatum and Fusarium) from the bloodstream is maximized using lysis-centrifugation techniques, such as the Isolator system (Wampole, Cranbury, NJ).

### Cerebrospinal Fluid Culture

Cerebrospinal fluid (CSF) should be transported quickly to the laboratory and then cytocentrifuged to concentrate organisms for microscopic examination. CSF is routinely cultured on blood agar and chocolate agar, which support the growth of common pathogens causing meningitis. If tuberculosis is suspected, cultures for mycobacteria should be specifically requested. Culture of larger volumes of CSF (>5 mL) significantly improves yield of mycobacteria.

Historically, rapid antigen detection tests for bacterial pathogens such as Haemophilus influenzae type b and Streptococcus pneumoniae were used to attempt to detect organisms in CSF without the need for culture. These techniques have now been proven to lack sensitivity and, in some cases, specificity. It has been demonstrated that a cyto- spin Gram stain is as sensitive as bacterial antigen tests for detection of microorganisms in CSF. In contrast, the cryptococcal antigen test can be useful when cryptococcal meningitis is suspected. Historically, India Ink preparations were used to detect Cryptococcus in CSF.

### Table 170-1: Stains Used for Microscopic Examination

<table>
<thead>
<tr>
<th>TYPE OF STAIN</th>
<th>CLINICAL USE</th>
</tr>
</thead>
<tbody>
<tr>
<td>Gram stain</td>
<td>Stains bacteria (with differentiation of Gram-positive and Gram-negative organisms), fungi, leukocytes, and epithelial cells</td>
</tr>
<tr>
<td>Potassium hydroxide (KOH)</td>
<td>A 10% solution dissolves cellular and organic debris and facilitates detection of fungal elements in clinical specimens</td>
</tr>
<tr>
<td>Calcofluor white stain</td>
<td>Nonspecific fluorochrome that binds to cellulose and chitin in fungal cell walls, can be combined with 10% KOH to dissolve cellular material</td>
</tr>
<tr>
<td>Ziehl-Neelsen and Kinyoun stains</td>
<td>Acid-fast stains, using basic carbolfuchsin, followed by acid–alcohol decolorization and methylene blue counterstaining</td>
</tr>
<tr>
<td></td>
<td>Acid-fast organisms (e.g., Mycobacterium) resist decolorization and stain pink</td>
</tr>
<tr>
<td></td>
<td>A weaker decolorizing agent is used for partially acid-fast organisms (e.g., Nocardia, Cryptosporidium, Cyclospora, Isospora)</td>
</tr>
<tr>
<td>Auramine-rhodamine stain</td>
<td>Acid-fast stain using fluorochromes that bind to mycolic acid in mycobacterial cell walls and resist acid–alcohol decolorization; usually performed directly on clinical specimens</td>
</tr>
<tr>
<td></td>
<td>Acid-fast organisms stain orange-yellow against a black background</td>
</tr>
<tr>
<td>Acridine orange stain</td>
<td>Fluorescent dye that intercalates into DNA, used to aid in differentiation of organisms from debris during direct specimen examination, and also for detection of organisms that are not visible with Gram stain</td>
</tr>
<tr>
<td></td>
<td>Bacteria and fungi stain orange, and background cellular material stains green</td>
</tr>
<tr>
<td>Lugol iodine stain</td>
<td>Added to wet preparations of fecal specimens for ova and parasites to enhance contrast of the internal structures (nuclei, glycogen vacuoles)</td>
</tr>
<tr>
<td>Wright and Giemsa stains</td>
<td>Primarily for detecting blood parasites (Plasmodium, Babesia, and Leishmania), detection of amoeba in preparations of cerebral spinal fluid, and fungi in tissues (yeasts, Histoplasma)</td>
</tr>
<tr>
<td>Trichrome stain</td>
<td>Stains stool specimens for identification of protozoa</td>
</tr>
<tr>
<td>Direct fluorescent-antibody stain</td>
<td>Used for direct detection of a variety of organisms in clinical specimens by using specific fluorescein-labeled antibodies (e.g., Pneumocystis jiroveci, many viruses)</td>
</tr>
</tbody>
</table>
but this method is insensitive compared to the antigen detection assay.

In the postvaccine era, the epidemiology of infectious meningitis is rapidly changing, and acute bacterial meningitis is now a relatively infrequent event in North America. Many CSF infections are associated with shunts or other hardware, and Propionibacterium and coagulase-negative staphylococci are the organisms most frequently isolated from shunt infections. The laboratory should include media to facilitate the growth of Propionibacterium in CSF specimens received from neurosurgery patients.

**Urine Culture**

Urine for culture (including colony count) can be obtained by collecting clean-voided midstream specimens, by catheterization, or by suprapubic aspiration. Urine samples collected by placing bags on the perineum are unacceptable for culture because samples are often contaminated. Rapid transport of urine to the laboratory (<2 hr) is imperative, and delay in transport or plating of specimens renders colony counts unreliable. Refrigeration or urine transport devices with boric acid preservative may be used when delay is unavoidable.

The specific colony counts used to define growth in a urine culture as “significant” are somewhat controversial and vary somewhat by laboratory. Urine obtained by suprapubic aspirate is normally sterile, and thus any organism growth is typically considered significant. Urine collected by catheterization is likely to reflect infection if there are ≥10^5 to 10^6 organisms/mL. Clean-voided urine is considered abnormal if ≥10^2 to 10^3 organisms/mL are present.

**Genital Culture**

*N. gonorrhoeae* is a fragile organism, and collection and transport in special medium is essential for efficient recovery. Selective agar, such as modified Thayer-Martin medium, should be used to enhance recovery of *N. gonorrhoeae* in clinical specimens, such as genital, anorectal, and pharyngeal swabs. Antimicrobial resistance is increasing in *N. gonorrhoeae*, although few clinical laboratories have the ability to perform antimicrobial susceptibility testing for this organism. In pediatric patients, the identification of an organism as *N. gonorrhoeae* should be confirmed using 2 independent methods.

Specimens for *Chlamydia trachomatis* culture are obtained by cotton-tipped, aluminum-shafted urethral swabs. Endocervical specimens, using swabs with aluminum or plastic shafts, should be collected by rubbing the swab vigorously against the endocervical wall to obtain as much cellular material as possible. *C. trachomatis* is an obligate intracellular organism and is cultured by inoculation into cell culture systems, followed by immunofluorescent staining with monoclonal antibody against the organism. Nonculture methods such as enzyme immunoassay (EIA) tests, direct immunofluorescent staining by monoclonal antibodies, and DNA amplification methods are widely used and are more cost-effective than culture.

Although nucleic acid amplification assays (NAAT assays) for *N. gonorrhoeae* and *C. trachomatis* are not FDA cleared for use in children, these assays are frequently used in this population to detect these organisms in urine specimens, endocervical and vaginal swabs, and penile swabs. The NAAT assays exhibit superior sensitivity compared to culture-based techniques. Some laboratories take the approach of confirming all NAAT-positive specimens with an alternative NAAT test that detects an alternative genetic target.

**Throat and Respiratory Culture**

Streptococcal pharyngitis and tonsillitis is a common diagnosis in pediatric patients; vigorous swabbing of the tonsillar area and posterior pharynx can be done to obtain a specimen for detection of group A streptococcus (*Streptococcus pyogenes*). Rapid antigen detection assays are frequently used when group A streptococcus pharyngitis is suspected. Negative rapid antigen assays should be confirmed using culture-based techniques. NAAT assays for detection of group A streptococci are also being used with increasing frequency. Most laboratories screen throat cultures exclusively for the presence of group A streptococci. However, large colony variants of group C and group G streptococci also cause pharyngitis, but are not associated with the same postinfectious sequelae attributed to group A streptococci; laboratory practices for detecting and reporting group C and group G streptococci are variable and an area of controversy.

In addition to the detection of pathogenic streptococci, the clinical laboratory may query for diphtheria, gonococcal pharyngitis, or infection with *Arcanobacterium haemolyticum* in throat specimens. The laboratory should be notified if any of these pathogens are suspected to ensure that appropriate methods are used to recover these organisms if present.

Cultures for *Bordetella pertussis* can be obtained by aspiration or swabbing of the nasopharynx using a Dacron or calcium alginate swab. The aspirate or swab is inoculated onto special charcoal-blood (Regan-Lowe) or Bordet-Gengou media, although molecular assays are now frequently used for detection of *B. pertussis* in these specimens.

The cause of lower-respiratory-tract disease in children is frequently difficult to confirm microbiologically because of the challenge of obtaining adequate sputum specimens. Gram-stained smears of specimens should be performed to assess the adequacy of sputum samples; specimens with large numbers of epithelial cells (>10 per high-powered field) or with few neutrophils are unsuitable for culture, as there is a lack of correlation between upper respiratory tract flora and organisms causing lower-respiratory tract disease. For patients with cystic fibrosis, special media should be used to detect pathogens important in cystic fibrosis, such as *Burkholderia cepacia*.

Endotracheal aspirates from intubated patients may be useful if the Gram stain shows abundant neutrophils and bacteria, although pathogens recovered from such specimens might still reflect only contamination from the endotracheal tube or upper airway. Quantitative cultures of bronchoalveolar lavage fluid may be valuable for distinguishing upper respiratory tract contamination from lower tract disease.

If infection with *Legionella* is suspected, the laboratory should be alerted so that the specimen can be inoculated to special media (such as buffered charcoal yeast extract agar) to facilitate the recovery of this pathogen. The *Legionella* urinary antigen test is a sensitive and specific, noninvasive method for rapid detection of *Legionella pneumophila* serogroup 1.

The diagnosis of pulmonary tuberculosis in young children is best made by culture of early-morning gastric aspirates, obtained on 3 consecutive days. Sputum induction for obtaining specimens for mycobacterial culture has also proved useful in young children but requires skilled personnel and containment facilities to prevent exposure of healthcare workers. Cultures for *Mycobacterium tuberculosis* should be processed only in laboratories equipped with appropriate biologic safety cabinets and containment facilities. NAAT tests for detection of *M. tuberculosis* in smear-positive respiratory specimens are becoming more widely available.

**Detection of Enteric Pathogens**

In pediatric patients with diarrheal illnesses, culture of stool for enteric pathogens may be requested. A fresh stool specimen is preferred, but is not always possible to obtain. If there is an unavoidable delay in specimen transport, the specimens should be placed into an appropriate transport medium, such as Cary-Blair. Rectal swabs for enteric culture are also acceptable specimens if the swab is visibly soiled. In general, enteric cultures should be performed on specimens from outpatients or patients who have been hospitalized for fewer than 3 days, as nosocomial acquisition of an enteric pathogen is very unusual.

Stool specimens are typically plated on a series of selective and differential media to decrease the overgrowth of normal flora and recover pathogenic organisms if present. The specific pathogens queried vary by laboratory. Most laboratories in North America will routinely culture for *Salmonella*, *Shigella*, *Campylobacter*, and Shiga toxin-producing strains of *Escherichia coli*. The CDC recommends that all laboratories use an agar-based medium for recovery of *E. coli* O157 in addition to an assay for detection of Shiga toxin production for all specimens submitted for enteric culture. Practices surrounding the routine culture for *Yersinia enterocolitica*, *Vibrio cholerae*, *Edwardsiella*, *Aeromonas*, and *Plesiomonas* will vary with local epidemiology, and the...
laboratory should always be notified if one of these pathogens is specifically suspected.

Clostridium difficile is an important cause of antibiotic-associated diarrhea. C. difficile was long characterized as a nosocomial pathogen of older adults, but community-associated disease is emerging and the incidence and severity of C. difficile infection in children is increasing. Although for many years laboratories relied on ELAs for detection of C. difficile toxins, these assays lack adequate sensitivity. Laboratories use nucleic acid detection methods to aid in the diagnosis of C. difficile. Testing for C. difficile in children <1 yr of age should be discouraged as a result of the high incidence of colonization in this patient population.

Viruses are an important cause of gastroenteritis in pediatric patients. Methods for viral detection will vary but may include antigen detection (e.g., for rotavirus or adenovirus 40/41) or nucleic acid detection methods (such as for norovirus).

In North America, the burden of parasitic gastroenteritis is low. Complete microscopic exams for ova and parasite detection in stool samples is usually of low yield, and antigen detection assays for Cryptosporidium and Giardia, the most commonly encountered agents, are sensitive and cost-effective methods for detection of these pathogens.

Multiplex nucleic acid detection tests for simultaneous detection of a dozen or more enteric pathogens, including bacteria, viruses, and parasites are emerging. When it is not completely clear how these assays will be deployed by clinical laboratories.

Culture of Other Fluids and Tissues
Abscesses, wounds, pleural fluid, peritoneal fluid, joint fluid, and other purulent fluids are cultured onto solid agar and, in some cases, broth media. Whenever possible, fluid rather than swabs from infected sites should be sent to the laboratory, because culture of a larger volume of fluid can detect organisms present in low concentration. Anaerobic organisms are involved in many abdominal and wound abscesses. These specimens should be collected and transported to the laboratory rapidly in anaerobic transport tubes.

Although Staphylococcus aureus is the most common cause of bone and joint infections, Kingella kingae is an important cause of septic arthritis in children, especially in children <4 yr of age. The detection of K. kingae is maximized by inoculation of synovial fluid into blood culture broth in addition to plating on solid medium, as well as by molecular detection of K. kingae in specimens from young patients with suspected septic arthritis.

Screening Cultures
Clinical laboratories may perform surveillance cultures for specific pathogens either to assist infection control in identifying patients requiring contact isolation or for outbreak investigation. Screening cultures for detection of methicillin-resistant S. aureus or vancomycin-resistant enterococci may be routinely performed in certain patient populations. In addition, hospitals with carbapenem-resistant Enterobacteriaceae may screen patients for rectal carriage of these organisms. Chromogenic media are frequently used for this purpose. These media contain proprietary compounds to select for the agent of interest and result in growth of colored colonies to identify pathogens of interest.

ANTIMICROBIAL SUSCEPTIBILITY TESTING
Antimicrobial susceptibility tests are generally performed on organisms of clinical significance for which standards and interpretive criteria for susceptibility testing exist. In North America, most laboratories use commercial, automated systems for susceptibility testing. The output from these systems is a minimum inhibitory concentration (MIC) value and interpretation of that value as susceptible, intermediate, or resistant. The next most common technique is Kirby-Bauer disk diffusion, in which a standardized inoculum of the organism is seeded onto an agar plate. Antibiotic-impregnated filter paper disks are then placed on the agar surface. After overnight incubation, the zone of inhibition of bacterial growth around each disk is measured and compared with nationally determined standards for susceptibility or resistance.

A less-commonly used technique is broth or microbroth dilution testing. A standard concentration of a microorganism is inoculated into serially diluted concentrations of antibiotic, and the MIC in µg/mL, the lowest concentration of antibiotic required to inhibit growth of the microorganism, is determined. The E-test is a hybrid of disk diffusion and broth dilution and can be used to determine the MIC of individual antibiotics on an agar plate. It uses a paper strip impregnated with a known continuous concentration gradient of antibiotic that diffuses across the agar surface, inhibiting microbial growth in an elliptic zone. The MIC is read off the printed strip at the point where the zone intersects the strip. Major advantages of the E-test are reliable interpretation, reproducibility, and applicability to organisms that require special media or growth conditions.

In addition to providing data to guide the treatment of individual patients, laboratories use aggregate susceptibility testing data to generate institution-specific antibiogram reports. These reports summarize susceptibility trends for common organisms and can be used to guide empirical therapy prior to the availability of specific susceptibility testing results.

Antimicrobial susceptibility patterns are rapidly changing as microbes evolve new resistance mechanisms. Recommendations for performance standards for antimicrobial susceptibility tests and their interpretation are regularly updated by the Clinical and Laboratory Standards Institute.

FUNGAL CULTURES
Special growth media is used to recover fungi, both yeasts and molds, in clinical specimens. As most fungi prefer reduced temperature, and some species grow slowly, fungal cultures are incubated at 30°C (86°F) for 4 wk.

Most yeasts are identified using methods similar to those used for bacteria. In contrast, the identification of filamentous fungi has not changed in nearly a century. The laboratory takes into consideration the growth rate, color, and colony characteristics of an isolate and then prepares the specimen in lactophenol alanine blue for microscopic evaluation. These features in aggregate are used to identify the isolate. In some cases, DNA sequencing is used for fungal identification and MALDI-TOF MS is also emerging for identification of filamentous fungi. All manipulations of filamentous fungi should take place in the biologic safety cabinet to avoid infecting laboratory personnel and prevent laboratory contamination.

Antigen detection assays are also available for some fungal pathogens such as Cryptococcus neoformans and H. capsulatum. Assays to detect galactomannan, a molecule found in the cell wall of Aspergillus, are commercially available and increasingly used to assist in making the diagnosis of invasive aspergillosis in immunocompromised populations.

POINT-OF-CARE DIAGNOSTICS
Some assays to detect infections may be performed in the office setting, provided the site is certified as meeting appropriate quality-assurance standards specified by the Clinical Laboratory Improvement Amendments (CLIA) of 1988. These include procedures listed under the category of "provider-performed microscopy" such as wet mounts, potassium hydroxide preparations, pinworm examinations, and urinalysis.

Many pediatric offices perform rapid antigen testing for detection of group A streptococcal pharyngitis. The sensitivity of point of care testing is dependent upon specimen collection technique, the type of kit used and on the concentration of streptococci present in the sample. However, in light of the fact that up to 30% of group A streptococcal rapid antigen tests are falsely negative, it is recommended that all negative results should be confirmed by culture.

Office laboratories licensed to perform waived tests are limited to performing these tests and avoid having to undergo inspections and provide the site is certified as meeting appropriate quality-assurance standards specified by the Clinical Laboratory Improvement Amendments (CLIA) of 1988. These include procedures listed under the category of "provider-performed microscopy" such as wet mounts, potassium hydroxide preparations, pinworm examinations, and urinalysis. Any office laboratory performing
Gram stains or cultures must comply with the same requirements and inspections for quality assurance, proficiency testing, and personnel requirements as fully licensed microbiology laboratories.

**LABORATORY DETECTION OF PARASITIC INFECTIONS**

Most parasites are detected by microscopic examination of clinical specimens. *Plasmodium* and *Babesia* can be detected in stained blood smears, *Leishmania* can be detected in stained bone marrow smears, and *Entamoeba histolytica*, and *Giardia lamblia* can be detected in stained fecal smears (see Table 170-1). Serologic tests are important in documenting exposure to certain parasites that are not typically found in stool or blood, and thus are difficult to demonstrate in clinical specimens, such as *Trichinella*.

*Trichinella* is a relatively common parasitic infection in pediatric patients. A diagnosis of *trichinella* can be made by evaluating a "pinworm prep." The best time to obtain this specimen is first thing in the morning, before the patient has bathed or had a bowel movement. A piece of clear scotch tape is pressed onto the perianal region of the patient and then the tape is applied to a clear microscope slide. The slide is then examined for recovery of pinworm eggs or worms.

Fecal specimens should not be contaminated with water or urine, because water can contain free-living organisms that can be confused with human parasites, and urine can destroy motile organisms. Mineral oil, barium, and bismuth interfere with the detection of parasites, and specimen collection should be delayed for 7-10 days after ingestion of these substances. Because *Giardia* and many worm eggs are shed intermittently into feces, a minimum of 3 specimens on nonconsecutive days are required to adequately exclude the diagnosis of an enteric parasite. Because many protozoan parasites are easily destroyed, collection kits with appropriate stool preservatives (commonly a 2-vial system with formalin and polyvinyl alcohol fixatives) should be used if delay between time of specimen collection and transport to the laboratory is anticipated.

Ova and parasite examination of fecal specimens includes a wet mount (to detect motile organisms if fresh stool is received), concentration (to improve yield), and permanent staining, such as trichrome, for microscopic examination. *Cryptosporidium*, *Cyclospora*, and *Isospora* are detected by modified acid-fast stain, and microsporidia by a modification of the trichrome stain. In addition, *Cyclospora* and *Isospora* autofluoresce under UV microscopy. The laboratory should be alerted if these parasites are suspected. Detection of certain intestinal parasites, especially *Giardia* and *Cryptosporidium*, can be simplified by using antigen detection tests.

Amebic encephalitis, caused by *Acanthamoeba*, *Balamuthia*, or *Naegleria*, is a rare but devastating and rapidly progressive disease. Special laboratory stains and procedures are required to detect these organisms. The laboratory should be notified if this infection is suspected.

Rapid antigen detection tests for *Plasmodium* species are available. The sensitivity and specificity of these tests vary depending on the burden of parasite in the sample, and the specific *Plasmodium* species. In general, these tests are most sensitive for detecting *Plasmodium falciparum* and least sensitive for detecting *Plasmodium malariae*. These tests are particularly useful for laboratories lacking personnel trained in evaluation of thick and thin smears for malaria, or to provide a rapid preliminary result while awaiting microscopy. All positive and negative rapid malaria assays should be confirmed with blood smear analysis.

*Trichomonas vaginalis* is a sexually transmitted protozoan parasite that can also be transmitted on household fomites. Infected individuals may be asymptomatic or may have mild inflammation or severe inflammation and discomfort. *Trichomonas* may be detected using a wet mount, but this method is insensitive. Rapid antigen assays are available. Culture-based detection or nucleic acid amplification techniques are the most sensitive way to make the diagnosis.

**SEROLOGIC DIAGNOSIS**

Serologic tests are primarily used in the diagnosis of infectious agents that are difficult to culture in vitro or detect by direct examination, such as *Bartonella*, *Francisella*, *Legionella*, *Borreli* (Lyme disease), *Treponema pallidum*, *Mycoplasma*, *Rickettsia*, some viruses (HIV, Epstein-Barr virus [EBV], hepatitis A virus), and parasites (*Toxoplasma*, *Trichinella*).

Antibody tests may be specific for immunoglobulin (Ig) G or IgM or can measure antibody response regardless of immunoglobulin class. In very general terms, the IgM response occurs earlier in the illness, generally peaking at 7-10 days after infection, and usually disappears within a few weeks, but for some infections (e.g., hepatitis A, West Nile Virus) it can persist for months. The IgG response peaks at 4-6 wk and often persists for life. Because the IgM response is transient, the presence of IgM antibody in most cases correlates with recent infection. Methods for IgM antibody detection are difficult to standardize, however, and false-positive results commonly occur with some tests. The presence of IgG antibody can indicate new seroconversion or past exposure to the pathogen. To confirm a new infection using IgG testing, it is essential to demonstrate either seroconversion or a rising IgG titer. A 4-fold increase in a convalescent titer obtained 3-4 wk following the acute titer is considered diagnostic in most situations. In neonates, interpretation of serologic tests is very difficult because of passive transfer of maternal IgG that can persist for 6-18 mo after birth.

Context is extremely important in the interpretation of serologic findings. Important considerations are the ability of the host to mount an immune response, the background rate of seropositivity (especially for IgG detection assays), and, for some diseases, the antibody titer. In addition, interpretation of some serologic assays, such as those used to diagnose Lyme disease, are problematic because of lack of specificity of the immunoenzymeassays. A confirmatory immunoblot (Western blot) is required for all positive and equivocal EIA results for Lyme disease.

**LABORATORY DIAGNOSIS OF VIRAL INFECTIONS**

Viral diseases are extremely important in pediatrics, and diagnostic virology has long been important to pediatric practice, especially in the inpatient setting.

**Specimens**

Specimens for viral diagnosis are selected on the basis of knowledge of the site that is most likely to yield the suspected pathogen. When evaluating patients with acute viral infections, specimens should be collected early in the course of infection when viral shedding tends to be maximal. Swabs should be rubbed vigorously against mucosal or skin surfaces to obtain as much cellular material as possible and sent in viral transport media that contain antibiotics to inhibit bacterial growth. Rectal swabs should contain visible fecal material. "Flocked" swabs have been shown to provide more material for the laboratory with consequent improvement in the performance of diagnostic tests.

Fluids and respiratory secretions should be collected in sterile containers and promptly delivered to the laboratory. All specimens should be transported on ice if delay is anticipated. Freezing specimens, especially at −20°C (−4°F), can result in a significant decrease in culture sensitivity. Consultation with the laboratory is recommended, because some commercial diagnostic test kits used by laboratories may require specific collection devices.

Laboratory diagnosis of viral infections may be by electron microscopy, antigen detection, virus isolation in culture, serologic testing, or molecular techniques to detect viral nucleic acids. In the past few years, molecular tests have emerged as the primary means for detecting viral infections, with some virology laboratories abandoning the use of viral culture altogether. Serologic testing still has a role, especially for arboviral infections such as West Nile, acute EBV infections, HIV, hepatitides A to C, and diseases of childhood such as measles, rubella, and mumps. Serology is also uniquely useful for defining immunity to specific viral infections.

**Antigen Detection Tests**

Immunofluorescent-antibody (IFA) techniques or other methods, such as EIA, that use antibodies to detect viral antigens directly in clinical specimens to permit rapid identification of viruses, were the mainstay
of the diagnosis of respiratory viral infections but are now being replaced by molecular tests. Smears of cellular material from respiratory secretions stained by immunologic reagents can identify the antigens of respiratory syncytial virus (RSV), adenovirus, influenza A and B viruses, parainfluenza virus types 1-3, and human metapneumovirus within 2-3 hr after the specimen is received. The sensitivity of IFA staining for RSV exceeds that of culture in many laboratories. For influenza A and B, IFA sensitivity approaches that of culture, whereas for parainfluenza viruses and adenoviruses, sensitivity of IFA is lower. Novel influenza strains, such as the one responsible for H1N1 pandemic influenza, may be poorly detected by IFA and other antigen detection techniques and require molecular tests for optimal sensitivity.

Sensitive IFA staining techniques are also commercially available for identifying varicella-zoster virus and herpes simplex virus (HSV). These specific methods have supplanted the Tzanck smear for multinucleated giant cells characteristic of varicella-zoster virus or HSV infections. A method for detecting cytomegalovirus (CMV) pp65 antigen in blood of immunocompromised patients is also available but is being replaced by molecular testing. IFA is not useful for detecting viruses in specimens that do not contain an adequate number of infected cells.

Rapid antigen tests usually based on lateral flow immunochromatography have been approved by the FDA for detection of influenza A and B and RSV. Some of these tests have “waived” status under CLIA, meaning that they can be performed by personnel who are not trained laboratory technologists, with relatively little formal quality control other than controls that are incorporated into the test devices. Some require as little as 10 min to perform. Consequently, these tests can be performed in a doctor’s office or an emergency unit. Sensitivity in children is higher than in adults and is in the range of 50-80%. Rapid antigen tests can be useful in managing patients with acute respiratory infections, provided the caregiver keeps in mind that a negative test does not rule out the diagnosis of influenza or RSV. Positive tests that are properly read tend to be reliable, but it is also important to keep in mind that the presence of a virus such as influenza or RSV does not rule out the presence of concomitant bacterial infection.

In addition to their role in respiratory virus infections, antigen-detection EIA tests are commonly used for the diagnosis of viruses that are difficult to culture, such as rotavirus, enteric adenovirus, and hepatitis B virus. The detection of the p24 antigen of HIV along with HIV antibodies is included in “fourth-generation” EIA tests used for the diagnosis of HIV.

**Viral Culture**

Viruses require living cells for propagation; the cells used most often are human- or animal-derived tissue culture monolayers, such as human embryonic lung fibroblasts or monkey kidney cells. Historically, in vivo methods such as inoculation of suckling mice were also used, but are rarely used today. Viral growth in susceptible cell culture is usually accomplished by detecting characteristic cytopathic effect that is visible by light microscopy under low magnification in the cultured cells. For some viruses (e.g., influenza, parainfluenza, and mumps viruses), this method is supplemented by hemadsorption, based on the production of virally encoded hemagglutinins on infected cell membranes that cause adherence of erythrocytes to infected cells. The most reliable confirmatory method for viral detection in cell culture involves fluorescein- or enzyme-labeled monoclonal antibody staining of infected cell monolayers. An important technical improvement in respiratory viral cultures is the development of cell culture systems that include more than 1 type of cell (R-Mix, Diagnostic Hybrids/Quidel, San Diego, CA) and employ IFA staining for virus detection. This system provides results in 16-48 hr from the time the specimen is received in the laboratory, compared to 2-10 days for conventional cultures. Cell culture methods are now being steadily replaced by molecular tests, which are faster, may be more sensitive, and have the potential to detect viruses that do not grow readily in cell cultures.

**Molecular Diagnostics**

Most molecular tests to detect viruses use the polymerase chain reaction (PCR) and other nucleic acid amplification tests. The first application of PCR to become widely accepted was a test to detect HSV DNA in CSF in patients with possible HSV encephalitis. The first FDA-cleared test for this purpose was approved in 2014. Many laboratories still use laboratory-developed tests, whose performance characteristics must be validated as specified by CLIA. The consequence of this situation is that testing is not standardized and the performance characteristics of this testing (sensitivity and specificity) may vary from laboratory to laboratory. At its best, PCR has sensitivity and specificity greater than 95% for HSV encephalitis. PCR is also increasingly used to diagnose mucocutaneous HSV and varicella-zoster virus infections. This testing is more sensitive than virus culture and provides a more rapid turnaround time.

An FDA-cleared test for enterovirus in CSF (GeneXpert, Cepheid, Sunnyvale, CA) provides sensitive detection of enteroviruses with a performance time of approximately 3 hr. Because this testing is simple to perform, some hospital laboratories are able to offer testing at all times, thus maximizing the clinical utility of the test. The parechoviruses, which may cause illnesses similar to those caused by enteroviruses, especially in infants <6 mo of age, must be detected by separate molecular assays. No parechovirus assays are currently approved by the FDA.

FDA-cleared molecular tests for respiratory viruses are increasingly replacing antigen detection and culture. Several FDA-cleared multiplex molecular tests are available for detection of influenza A and B and RSV. As of 2014, 4 multiplex tests that detect larger numbers of respiratory viruses are also available (Table 170-2). Viruses detected by these tests include influenza A and B, RSV, parainfluenza 1-4, human metapneumovirus, adenovirus, rhinovirus/enterovirus, and coronaviruses OC43, 229E, NL63, and OC43. The performance of each test for each of the viral targets must be approved or cleared by the FDA, so the tests vary among one another in the specific virus targets for which they have achieved FDA approval/clearance (Table 170-2). In addition, 1 of the tests (FilmArray) is also cleared for the detection of the bacterial agents *B. pertussis, Mycoplasma pneumoniae*, and *Chlamydia pneumoniae*. This test is also notable because the performance time is only

*Cleared by the FDA as of July, 2013. Other versions that detect additional viruses are available outside of the United States.

¹Detects rhinoviruses and enteroviruses but does not distinguish between them.

Ad, adenovirus; AH1, influenza A, hemagglutinin type 1; AH3, influenza A, hemagglutinin type 3; flu A, influenza A; flu B, influenza B, HMPV, human metapneumovirus, PIV, parainfluenza virus; RSV, respiratory syncytial virus.
approximately 1 hr, permitting very rapid turnaround time. A multi-
plex assay for the detection of viruses (norovirus and rotavirus), as well
as important bacterial and parasitic pathogens (xTAG Gastrointestinal
Panel, Luminex, Austin, TX), has been cleared by the FDA and similar
tests are being developed by numerous other companies.

Another important area of application of molecular testing is the
detection of viruses in the blood. FDA-approved assays to detect HIV
and hepatitis C RNAs are essential for the management of these infec-
tions, including the prevention of transmission from mother to infant.
Hepatitis B molecular testing is also increasingly used. In addition,
molecular testing is now widely used for viruses that cause systemic
disease in immunocompromised patients, especially CMV, EBV, HSV,
the BK polyomavirus, and adenovirus. For these viruses, as well as for
HIV and the hepatitisviruses, quantitative testing is required. An FDA-
approved PCR assay for the quantitative measurement of CMV DNA
in plasma is now available. In addition, international standards for
CMV have been developed. This is important because it makes possible
better comparability among different quantitative CMV assays if they
are each referenced to the international standard. Testing for the other
viruses must be carried out using laboratory-developed tests, sometimes
with the use of analyte-specific reagents, a class of reagents that
are regulated by the FDA although not incorporated into complete
diagnostic test kits.

Laboratory-developed PCR and other molecular assays are used by
some laboratories for numerous other viruses, including parvovirus
B19; human herpesvirus 6; mumps, measles, and rubella viruses; and
the JC polyomavirus.

Host gene expression patterns in whole blood have been used to
differentiate viral from bacterial infections. This microarray-based
assay may rapidly identify a viral or bacterial profile of host gene
expression reprise, thus greatly shortening the time to diagnosis and
potentially avoiding inappropriate treatment while suggesting indi-
cated therapies.

Dunn JJ, Hindiyeh MY: Clinical microbiology in pediatrics, Perspect Dev Pathol Feb 2010 [Epub ahead of print].

From the time of birth, the human infant is exposed to a myriad of microbes found on the mother and in the surrounding environment. Microbes rapidly form assemblages across exposed areas of the body, including the skin and enteral tract. The microbial communities are called the **microbiota** and make a substantial impact on short- and long-term physiology, including immunologic and metabolic development and function. Together the number of body-associated bacterial cells is estimated to be 10 times greater than the number of human cells in the body. In aggregate, the totality of the microbes, including their microbial genes and environmental interactions, constitute the microbiome, and the microbial genes in the human microbiome are estimated to exceed the number of human genes by at least 100-fold, together making a macroorganism with an inseparable collective physiology. Current evidence indicates that the microbiome evolves over the life span to influence health and disease.

**MEASURING THE MICROBIOME**
Prior knowledge of microbes on and around the human body was based on specific methods to cultivate organisms. Molecular technologies have revolutionized the identification of poorly cultivatable microbes, rare microbes, and microbes in complex communities like those associated with the human body (Fig. 171-1). The development of the polymerase chain reaction and the availability of modern nucleic acid sequencing have improved the sensitivity of detection of many organisms and have also resulted in the discovery of new organisms. Modern sequencing technologies, so-called next-generation sequencing platforms, allow sequencing in high volume and depth, with millions of sequences obtained from a single biologic sample. Three major approaches have utilized next-generation sequencing to understand the composition, diversity, and activity of the microbiome: (1) sequencing species-specific regions of genomes such as ribosomal RNA-encoding tracks and intergenic regions, (2) total DNA sequencing and assembly of sequence fragments into large genome pieces termed **metagenomics**, and (3) RNA transcript sequencing to decipher the transcriptional activity of a microbiome. New bioinformatics tools have allowed the analysis and comparison of the large datasets arising from these methods.

Two additional approaches to measure the microbiome have been rapidly developing as well. First, large-scale measurements of the peptide composition of the microbiota, called **proteomics**, have been increasingly used to describe the activity of a microbiome sample, as peptides provide information about the composition and function of a microbiome. Second, in a complementary approach called **metabolomics**, microbiome-derived metabolites are measured using advanced mass spectrometry techniques. Together, proteomics and metabolomics better describe the activity of a microbiome than the nucleotide-sequencing approaches; however, at this point in time, they provide less depth of resolution and specificity of the composition of a microbiome.

Despite the power of these new methodologies to interrogate the microbiome, they do not yet replace cultivation of microbes in many clinical circumstances. Cultivation of organisms still represents the most practical means to differentiate potential pathogenic species from more benign species and to provide key information such as susceptibility to antimicrobials.

**EARLY-CHILDHOOD DEVELOPMENT OF THE MICROBIOME**
In healthy, uncomplicated term deliveries, infants are believed to be sterile until birth. The rupture of the fetal membranes and subsequent delivery is likely the first major exposure to colonizing microbes. Exceptions may be prematurity as a complication of infection of the
fetal membranes and either subclinical or clinical chorioamnionitis, where molecular analyses suggest that in utero exposure to microbes is common. Mode of delivery has a major influence on the early-life microbiome, with vaginally delivered infants becoming acutely colonized with intestinal organisms that reflect the mother's vaginal tract and infants delivered by cesarian section becoming colonized with intestinal organisms reflective of the maternal skin.

In the term infant delivered by vaginal delivery, the first intestinal microbiota, so-called pioneering organisms, include aerobic organisms such as Enterobacteriaceae (e.g., E. coli), Streptococcaceae, and Staphylococcaceae. Some infants have anerobes in their early colonizing microbiota, including Clostridiales and Bacteroidales. However, anaerobes are uncommon, likely because of the aerobic environment of the neonatal intestinal tract, the underdeveloped mucus layer, and relatively high intestinal motility. Exclusive breastfeeding has been reported to result in high levels of bifidobacteria and Lactobacillus in the week following the start of feeding. These probiotic organisms have unique capacities to exclude would-be pathogens from colonization by sequestering nutrients and producing antimicrobial factors while stimulating the intestinal epithelium to tighten cellular junctions and express antimicrobial peptides. However, these genera have been notably deficient from some breastfed infant cohorts, particularly within the United States.

The premature infant is more likely to be delivered by cesarian section and will often be colonized with skin-related organisms such as coagulase-negative staphylococci, similar to the term infant delivered through a similar mode of delivery. However, the premature infant may fail to progress through the same stages of expansion and diversification of the microbiota over the 1st wk to mo of life as the term infant. The factors related to the delayed maturation are not fully clear but are predictably related to delayed or limited enteral feeding, normal environmental exposure to the household environment, and exposure to medical interventions such as antimicrobials.

The most significant shift in the intestinal microbiota appears to occur after weaning and the introduction of solid foods. As the infant transitions from breast milk to a solid food diet containing complex plant-derived polysaccharides, the microbiota begins to reshape progressively into a more mature composition beginning to resemble the adult microbiota. A partial transition occurs from aerobic and facultative anaerobes such as streptococci and coliform enterics like E. coli to more strict anaerobes such as Bacteroides spp.; however, more studies are required in large numbers of children to fully understand the developmental stages of maturation and the likeness to the mature, healthy adult state.

Currently, development of the oral and skin microbiomes in childhood is not well understood. Past studies revealed remarkable diversity of the composition of the microbiota within the oral cavity in the presence of full adult dentition, with an estimated 1,000 bacterial species. Even with oral health, there is substantial diversity in the gingiva of different types of teeth, so-called geodiversity, and the diversity changes dramatically with the development of oral disease such as periodontitis. However, the oral microbiome predentition, during tooth eruption and during the transition from primary to secondary dentition is currently poorly understood. Furthermore, the placement and removal of oral hardware for orthodontics is common in childhood and may produce important alterations in the microbiome of the oral cavity.

The adult skin microbiome displays a high degree of geodiversity—differences in composition depending on site and local physiology with major differences in dry and wet skin sites. However, the linkage between skin development in childhood and maturation of the skin microbiome remains a key subject of future study.

Social structure and family interactions likely play a large role in the development of the early life microbiome. Breast milk feeding provides a microbiologic link between mothers and infants, including transmission of probiotic-like organisms such as lactobacilli and bifidobacteria, each of which may have some protective effects including protection against diarrheal diseases and atopy. Pediatricians have long been aware of the infectious disease risks and benefits of daycare attendance, with examples of shared pneumococcal strains producing otitis media and outbreaks of respiratory syncytial virus infection and associations with reduced atopy, allergy, and possibly asthma. Family contacts are risks for acquisition of methicillin-resistant S. aureus and subsequent disease. Recent studies demonstrate that at least parts of the human microbiome are transmitted between household individuals and domesticated pets such as dogs and cats. For instance, family members share the same strains of E. coli known to produce urinary tract infections in 1 of the household members. There may be differences in the oral microbiota among infants for whom the parents did and did not use the practice of pacifier sucking for cleaning. Thus, development of the microbiome during childhood is a complex process that is just beginning to be understood.

**THE MICROBIOME AND PHYSIOLOGIC DEVELOPMENT**

The microbiome has increasingly complex roles in the development of mammalian physiology (Fig. 171-2). These include the development of the enteral tract, the immunologic system, the hematologic system, the metabolic-endocrine system, and the neurologic system. The details of how the microbiome contributes to these developmental processes in humans are still under intense investigation; however, modeling in other mammalian systems predicts that the microbiome will have a critical role.

**Microbiome and Metabolism**

Soon after entry into the physical world, the mammalian enteral tract is colonized and the interaction of early pioneering microbes in the enteral tract stimulates the development of the intestinal mucosa. In neonatal and juvenile animal models, delayed or absent intestinal colonization results in incomplete development of the epithelium, flattening of the intestinal crypts, loss of vasculature, and severely reduced enzymatic function, including alkaline phosphatase and glucosidases.

The enteric microbiota has a large number of roles in the physiology of the intestinal tract. In addition to its function in mucosal and systemic immune development as well as development and regeneration of the epithelium, the microbiota plays a role in key aspects of metabolism: (1) the digestion of otherwise indigestible plant polysaccharides; (2) production of vitamins and cofactors; (3) metabolism of xenobiotics, including clinically relevant drugs; and (4) stimulation of local and systemic metabolism, including lipid storage. Germ-free animals lacking the enteric microbiota have limited nutrient extraction and have a failure to thrive phenotype.

---

**Figure 171-2** Physiologic and pathologic roles of the microbiome relevant to pediatrics. The human microbiome has an impact on health and development from pregnancy through to adulthood, including infection and non-infection-related processes.
Mice born into a sterile environment have been colonized with human fecal microbial communities. Feeding of “humanized” mice diets with and without polysaccharides, akin to the weaning to solid food transition, results in dramatic alterations in central metabolites. “Humanized mice” transitioned from a polysaccharide-rich, low-fat diet to a more “Westernized” diet high in fat and monosaccharides under a blossoming of the phyla Actinobacteria and Firmicutes in the enteric microbiota with a commensurate reduction in Bacteroidetes, similar to observations of increased Firmicutes and reduced Bacteroidetes in obesity.

Common patterns of mature enteric microbiota community composition and predicted function may exist among humans. Sequencing of the fecal microbes from adults across multiple nations revealed 3 common patterns of microbial community compositions, called enterotypes. Significant increases in the proportions of Bacteroidetes, Prevotella, and Ruminococcus were found as sentinels of the different enterotypes, and these enterotypes could be identified in individuals from multiple continents, including North America, Europe, and Asia. The different enterotypes among infants and children are not well defined, with the possibility that mature, stable enterotypes form in the early postweaning period or after infancy. Breast milk and formula feeding enterotypes have been described, with notable enrichment of enteric Gram-negative bacteria such as E. coli and anaerobic Clostridia spp. among the formula-fed infants.

**Microbiome, Inflammation, and Immunity**

The organisms that compose the microbiome are critical for early immune programming, the development of immune tolerance, and overall maintenance of immune set points. Cells produce a variety of receptors to recognize microbial ligands, in a process called pattern recognition. In turn, microbes produce intentional and unintentional stimulation of those cellular receptors to activate and repress inflammatory pathways. Classic examples of such regulatory interactions include peptidoglycan on bacteria binding to Toll-like receptor 2 (in complex with Toll-like receptor 3 and Toll-like receptor 6), lipopolysaccharide of Gram-negative bacteria binding to Toll-like receptor 4, and glucans of fungi binding to the dectin receptor. The results of these receptor interactions include the production of chemokines and cytokines, cell differentiation and development, alteration in metabolism, and stimulation of cell death and survival programs, all contingent on the type of cell, the state of the cell, and the magnitude of stimulation.

Microbial stimulation of these microbial recognition systems is so critical in development that animals raised in the absence of microbes have diminished innate immune responses such as antimicrobial peptides at mucosal surfaces, dysregulated proinflammatory and immunologic tolerance responses, and reduced T- and B-cell populations. Following restoration of normal colonization weeks after being sterile, animals have long-term aberrant cytokine responses with hyperactive proinflammatory responses to stimuli, demonstrating the long-lasting consequences of altering early microbial acquisition. Different early life colonization patterns also correlate with long-term immune development. In a Scandinavian study, children with persistent early life E. coli colonization had higher sustained memory B-cell (CD3+CD20+CD27+) levels by 1.5 yr of life compared to children with lower levels of E. coli colonization, even despite abundant colonization with prototypical probiotic bacteria Lactobacillus spp.

**Microbiome-Neurobiologic Connections**

Emerging studies are demonstrating a gut–brain axis that may be altered by the composition and activity of the enteric microbiome. Investigations in animal models have shown that the microbiome alters the hypothalamic-pituitary-adrenal system. Germ-free mice have exaggerated stress–anxiety behavior accompanied by elevated corticosterone and adrenocorticotropic levels compared with conventionally colonized, pathogen-free mice. Functional MRI has shown that the ingestion of 5 strains of probiotic-like bacteria alters brain activity in humans, resulting in decreased brain responses to emotional attention tasks in sensory and emotional input regions of the brain. Although

the mechanism underlying these changes can only be inferred, the tractus solitarius and thus the vagus nerve appear to mediate the enteral tract–brain connection.

Another mechanism through which the enteric microbiome may alter brain activity is by the metabolites it produces. Administration of fermented milk with probiotic like organisms, most notably *Bifidobacterium animalis* subsp. *lactis*, to monozygotic human twins and to mice did not dramatically change the intestinal microbiome composition but did alter its transcriptional profiles, with a shift to increased carbohydrate fermentation to fatty acids, thought to attenuate sad emotional behavior in humans.

**CONTRIBUTIONS OF MICROBIOME TO DISEASE**

Studies demonstrate that some microbial communities may act in concert to exert negative health effects, whereas other communities may be restorative or resistant to disease. A number of examples of this concept of altered microbial communities, also termed dysbiosis, are provided in the sections to follow.

**Microbiome of Premature Birth**

While the etiology of premature birth is multifactorial, inflammatory conditions including subclinical and clinically overt infections of the mother and/or fetus have been proposed to be instigators of premature birth. Inflammatory biomarker profiling highlights this point, as women who proceed to preterm birth have increased angiotensin, interleukin 8, and tumor necrosis factor receptor 1, along with a number of race-specific alterations in additional cytokines and chemokines. Prior work reported that women experiencing preterm birth have increased vaginal colonization with *Gardnerella* spp. and *Lactobacillus crispatus*. There may be a lower diversity in microbiota of the posterior vaginal fornix of women experiencing preterm birth. A meta-analysis of early treatment of vaginosis with clindamycin prior to 22 wk of pregnancy demonstrated a reduction in spontaneous preterm birth at <37 wk, consistent with an association between dysbiosis of the pregnancy-associated microbiota and preterm birth.

Traditionally, the amniotic cavity and the fetus have been presumed to be sterile prior to the rupture of the fetal membranes and birth. However, several reports identify evidence for bacterial DNA in meconium with 2 predominant meconium types regardless of mode of delivery: (1) dominated by Enterobacteriaceae, and (2) dominated by Leuconostocaceae, Enterococcaceae, and Streptococcaceae. Furthermore, data indicate that the amniotic fluid in subclinical and clinically apparent chorioamnionitis has evidence of vaginal-derived microbes present, including poorly or noncultivatable organisms such as Mycoplasma spp., Ureaplasma spp., Bacteroidetes spp., Fusobacterium, *Neisseria* spp., and *Leptotrichia amnionii*. A correlation exists between the burden of intraamniotic organisms and the degree of prematurity. Microbial invasion of the amniotic space may lead to induction of inflammatory pathways through innate immune microbial pattern recognition receptors such as the Toll-like receptors. The result may be the induction of labor and physiologic stress on the fetus and mother. Exposure to microbial factors may have consequences on lung and intestinal development, setting the stage for postnatal pathology including necrotizing enterocolitis. Beyond the acute threat to the maternal–fetal dyad, chorioamnionitis may not produce the long-term neurodevelopmental consequences it once was thought to cause, with formerly premature infants born to women with chorioamnionitis having similar cognitive and neuropsychiatric outcomes even to age 18 yr as infants not exposed to chorioamnionitis.

**Changes in the Microbiome with Necrotizing Enterocolitis**

Necrotizing enterocolitis (NEC) is a devastating disease of the neonatal intestine that disproportionately affects severely premature infants who weigh less than 1,500 g at birth. The pathologic steps in NEC include intestinal inflammation with loss-of-barrier function, microbial invasion of the bowel, and eventual death of the affected bowel. Years of research implicated specific organisms as the cause of NEC in case
series; however, none of the proposed specific etiologies proved to be common to all cases of NEC and, instead, appeared to be the emergent organisms after serious intestinal pathology had ensued. Contemporarily, a model of dysbiosis of the early life intestinal microbiome has been favored in the pathogenesis of NEC. Epidemiologic studies in very-low-birthweight infants have demonstrated an association of cephalosporins and duration of antibiotic exposure with the development of NEC, consistent with the idea that shifts in the microbiota predispose to or incite NEC. Studies demonstrate decreased diversity of the microbiota preceding and during NEC. The NEC microbiota at the time of clinical symptoms resembles the microbiota 72 hr prior to onset but not the microbiota 1 wk prior to onset of symptoms, suggesting that a shift in the intestinal microbiota begins well in advance of the appearance of NEC. Some differences in early colonization following birth may portend an increased risk for NEC.

**Microbiome and Allergic Disorders**

Given the role of the microbiome in the development and modulation of innate and adaptive immune responses, considerable interest has been given to its role in the development and exacerbation of allergic conditions such as atopic dermatitis.

The microbiome of the skin has been studied prior to, during, and following treatment of flares of atopic dermatitis. Flares result in the loss of diversity of bacteria on the affected area, and treatment introduces new diversity. *S. aureus* and *Staphylococcus epidermidis* increase prior to and during atopic flares, whereas *Streptococcus* spp. and *Corynebacterium* spp. increase immediately preceding and during clinical improvement. In mice, oral treatment of infant animals with nonabsorbable antibiotics increases serum immunoglobulin (Ig) E, increases clinical symptoms such as itching, and produces atopic-like features. These data suggest that atopic dermatitis is influenced by the local skin microbiome and more distant microbiomes such as in the intestinal tract, also suggesting why the administration of oral probiotics such as *Lactobacillus* spp. may decrease atopic dermatitis with an accompanying shift in the T-cell Th1/Th2 balance and increased interferon-γ, which are part of immune tolerance.

The respiratory tract is a common site of allergic disease, and infections have long been associated with allergic exacerbations of the respiratory tract. Traditional teaching is that the lower respiratory tract is sterile; however, studies of the airway microbiome in healthy and asthmatic children and adults indicate that this teaching is incorrect. Measured through careful bronchoscopic sampling and cytology brushings, the airways have a diverse microbiota during good health.

Measurement of the microbiota in the lower respiratory tract of healthy and asthmatic children indicates significant differences. Past culture-based studies indicate that early life colonization of the neonatal respiratory tree by *H. influenzae*, *Moraxella catarrhalis*, and *S. pneumoniae* is associated with an increased risk for childhood asthma. These same organisms also are closely associated with exacerbations of asthma. *M. pneumoniae* has been proposed as a major bacterial inducer of childhood asthma exacerbations when infection is identified. The employment of culture-independent measurements of lower airway microbiota composition (see Fig. 171-1) indicates that children with asthma are more likely to have higher levels of Proteobacteria, including *H. influenzae*, as well as Firmicutes such as *Staphylococcus* spp. and *Streptococcus* spp. Remarkably, healthy children are more likely than age-matched asthmatic children to have lower airway Bacteroidetes, particularly *Prevotella* spp., a group of anaerobic bacteria. The association of healthy airways with a lower respiratory tree anaerobic bacterial population is surprising because the high oxygen tension environment has been assumed to be toxic to anaerobes. This study indicates that the airway environment is significantly different than previously understood, and the potentially protective attributes of a native health-associated microbiota needs to be studied to determine if these associations are also causal.

**Airway Microbiome of Cystic Fibrosis**

Cystic fibrosis is characterized by progressive airway disease and inflammation with acute exacerbations accompanied by loss of pulmonary function. Cystic fibrosis has long been known to have an age-dependent change in lower airway colonization, which starts in early childhood with *S. aureus* and *H. influenzae* and progressively shifts toward more intrinsically multidrug-resistant organisms, including the notoriously persistent and treatment-refractory bacteria *Pseudomonas aeruginosa* and *B. cepacia* complex. Culture-independent molecular analysis of the lung-associated microbiota in cystic fibrosis has revealed far more complex microbial communities than previously expected and has demonstrated an association with patient age and disease severity. In addition to the presence of a variety of previously unexpected airway organisms such as anaerobes and mycobacteria, disease severity is inversely related to the lower airway microbial community diversity with less advanced disease associated with greater species richness and evenness. In contrast, the loss of diversity, including the shift from less complex microbial communities to those dominated by *P. aeruginosa*, is strongly correlated with disease severity, and levels of *H. influenzae*, the early childhood colonizer, have a negative correlation with disease severity. Although antibiotics decrease the rate of progressive lung function, they also decrease the community diversity, thus suggesting a balance between a diverse microbiota and reducing the dominance of certain organisms such as *P. aeruginosa*.

**Microbiome During Antibiotic-Associated Diarrhea and Clostridium difficile Colitis**

Treatment with oral and parenteral antibiotics results in a rapid and significant alteration of the intestinal microbiota. Studies of normal individuals taking ciprofloxacin demonstrated dramatic but individualized responses to the antibiotic, with significant reductions in bacteria outside the expected spectrum of the antibiotic, emphasizing the intradependence of microbial community members on one another for their stability in the community as a whole. Furthermore, the response to ciprofloxacin among subjects varied by individual, suggesting different degrees of stability of the microbiota and resilience under stress such as antibiotics. In general, with the exception of some rare members of the community, the community was largely restored within 4 wk after the completion of the antibiotic course. Some antibiotics, such as amoxicillin-clavulanate, for which antibiotic-associated diarrhea is a well-known adverse event, produce a loss of *Clostridium* and *Bacteroides*, known to be important in the production of short-chain fatty acids (SCFA) and the metabolism of otherwise undigestible carbohydrates. Together, their loss may decrease the metabolic integrity of the intestinal epithelium that uses SCFA for energy while resulting in a high osmotic environment in which fluid is drawn into the intestinal lumen. Antibiotic-associated diarrhea may result from these combined effects.

One of the most serious complications from antibiotic exposure is the development of *C. difficile*-associated diarrhea (CDAD), which has high associated morbidity and even mortality. Microbiologic surveys suggest that *C. difficile* is a common constituent of the developing microbiota early in life with less prevalence over the life span. Over 30% of infants are colonized with *C. difficile* in the 1st mo of life, continuing until approximately 6 mo of age. By 1 yr of age, colonization ranges between approximately 15% and 70% and then declines through to adulthood, when carriage is estimated to be <3%. Although *C. difficile* has been found within the vaginal microbiota of pregnant women, vaginal delivery has not been associated with increased rates of neonatal *C. difficile* colonization, with vaginal and cesarean delivery having rates of colonization at 30% and 37%, respectively. CDAD has been reported to result in 35-45 hospitalizations per 10,000 pediatric admissions among children 1-9 yr of age.

Although the studies have not yet determined how the intestinal microbiome is altered preceding, during, and with resolution of CDAD in children, molecular studies of the intestinal microbiota in adults provide some details of the consequences of CDAD on the intestinal microbiota. Studies employing deep sequencing of stool from individuals with CDAD and *C. difficile* colonization without disease have revealed depletion of certain bacterial genera accompanying the presence of *C. difficile* colonization. These genera include *Blaattia,*
Pseudobutyryvibrio, Roseburia, Faecalibacterium, Anaerostipes, Sibdoli-
granulum, Ruminococcus, Streptococcus, Dorea, and Coprococcus. The
relationship of cause and effect and the events triggering the transition
from colonization to symptomatic disease remain unknown. Similar to
the studies of antibiotic-associated diarrhea, these studies also dem-
strate a reduction in butyrate-producing Clostridium spp., which are
proposed to be important for producing butyrate as an energy
sources for the intestinal epithelium and its robust integrity.

Although antibiotics such as metronidazole and vancomycin have
been employed to treat CDAD, traditional treatment does not elimi-
nate recurrent CDAD to the extent that might be expected. To address
this problem, fecal transplantation or administration of feces from
healthy donors to CDAD recipients is effective in treating CDAD and,
more importantly, superior to these antibiotics in reducing the likeli-
hood of recurrent disease. Accompanying clinical resolution is reple-
tion of Bacteroidetes and Clostridium clusters IV and XIVa with a
matched decrease in Proteobacteria. Most of the experience with fecal
transplantation has been gained from adults with only a single pub-
lished pediatrics report, although research studies are underway.

Microbiome and Association with Inflammatory
Bowel Disease

Crohn disease and ulcerative colitis are chronic inflammatory diseases
of the enteric tract and are believed to be the result of the intersection
of host susceptibility and a dysbiosis, an alteration in the intestinal
microbiota. Twin-twin studies indicate concordance rates in monozy-
gotic twins of 10-15% in ulcerative colitis and 30-35% in Crohn disease,
thus demonstrating a genetic component for each disease while high-
lighting environmental factors that likely induce and drive disease
progression. More than 150 single-nucleotide polymorphisms are asso-
ciated with the diseases, revealing potential defects in handling
microbes, including those involved in barrier function, innate immu-
nity, autophagy, adaptive immunity, and metabolism and cellular
homeostasis.

In inflammatory bowel disease (IBD), the microbiota undergoes a
shift in association with the disease throughout the intestinal tract.
Although considerable heterogeneity has been described, IBD is often
demonstrated to be accompanied by a decrease in bacteriodes, clo-
stridia, bifidobacteria, and Firmicutes. Reciprocally, outgrowths of
E. coli and other Enterobacteriaceae are described. Increased sulfur-
metabolizers have been described with IBD as well. Antibiotics along
with biologic therapies such as antibodies directed at neutralizing
tumor necrosis factor have been employed to manage the IBD dysbio-
sis and inflammatory reaction. Trials of fecal transplantation are
underway to determine if a noninflammatory microbiota from a
healthy donor may mitigate IBD symptoms and progression.

Microbiome of Obesity

Obesity and the metabolic syndrome are associated with notable
changes in the intestinal microbiome in terms of composition and
metabolic function, ultimately resulting in greater energy extraction
from the diet. “Typical” changes in the microbiome include an increase
in the ratio of the phyla Firmicutes : Bacteroidetes. Additional work has
indicated that Prevotellaceae, a family within the Bacteroidetes phylum,
may be specifically increased with obesity. However, there remains
considerable debate about obesity-specific changes in the microbiome,
as studies other than those mentioned previously have demonstrated
decreased Firmicutes : Bacteroidetes ratios in the fecal microbiota from
obese individuals compared to lean controls. Further studies show that
proportions of phyla-level groups may be less important than changes
in Firmicutes subgroups that produce butyrate, a known fatty acid
substrate easily acquired and utilized by the intestinal epithelium, and
thus ready calories for the host.

The intestinal microbiome benefits the host in important ways,
including enhancing caloric extraction from indigestible substrates
such as polysaccharides in the diet. The microbiome produces deg-
radative enzymes to break down these substrates where enzymes with
comparable functions, such as some glycosyl hydrolases, are not
encoded in the human genome. Molecular studies indicate that the
intestinal microbiome may also interact with the intestinal epithelium
in such a way as to alter general energy homeostasis and fat storage.
For instance, the intestinal microbiome may produce SCFA that, in
turn, alter endocrine peptide expression such as glucagon-like peptide
1 and peptide YY, which alter glucose homeostasis and satiety, respec-
tively. Furthermore through the production of SCFA and ketones, the
microbiota may alter sympathetic tone. Certain microbiomes are
known to suppress others to induce fastening-induced adipose factor
(also called angiopoietin-like protein 4), a lipoprotein lipase inhibitor
of intestinal, hepatic, and adipose origins. Colonization with a diverse
microbiota suppresses fastening-induced adipose factor expression,
and dietary supplementation of a Western diet with Lactobacillus para-
casei further suppressed otherwise high fastening-induced adipose
factor expression. Mice fed a Western diet developed adiposity, which
was transferrable to recipient lean mice following transplantation with
the obese mice microbiota. Reciprocally, obese mice treated with anti-
biotics experienced less insulin resistance, lower fasting glycemic
indices, and improved glucose tolerance compared to untreated
counterparts, further implicating the microbiome in these physiologic
changes.

Microbiome During Malnutrition

Malnutrition is a leading cause of morbidity and mortality across the
world. In its most severe form, malnutrition may result in kwashiorkor,
which is characterized by generalized edema, anorexia, fatty enlarged
liver, skin ulcerations, and irritability. Ready-to-use foods are employed
to try to restore nutrition in areas with severe food restrictions. Mono-
zygotic and dizygotic twins in Malawi were studied for the alterations
in the microbiome in association with moderate to severe malnutri-
tion, including kwashiorkor. Among the twins with discordant degrees
of malnutrition on food supplements, the twins with mild preexisting
malnutrition had intestinal microbiota that changed significantly over
the course of supplementation. In contrast, the twins with preexisting
kwashiorkor had microbiota with poor to no change in response to
nutritional supplementation. These findings were recapitulated to
some extent following transplantation of the twins’ microbiota into
previous sterile mice. Those mice receiving the microbiota of Malawan
twins with kwashiorkor experienced more dramatic weight loss on a
Malawan-type diet and more rapid loss of their weight gain once off
ready to use food supplements than did mice transplanted with the
feces of more healthy twins. The mice with the transplanted kwashiorkor
microbiota had sustained problems with carbohydrate, lipid, and
amino acid metabolism despite nutritional supplementation of the
Malawan diet. Together these data indicate that severe malnutrition
results from the combination of nutritional deficits and a microbiome
with altered metabolic capabilities that are not readily restored with
contemporary nutritional supplementation treatments.

THERAPEUTIC MANIPULATION
OF THE MICROBIOME

Therapeutic manipulation of the microbiome falls into 5 general cat-
egories: (1) antimicrobials, (2) prebiotics, (3) probiotics, (4) postbiot-
ics, and (5) fecal transplantation. Brief mention of fecal transplantation
was discussed in the sections on C. difficile diarrhea and IBD. Postbiot-
ics are nonviable microbial components or metabolites that may alter
the microbiota or produce physiologic changes in the host. Insufficient
data exist to warrant a discussion of postbiotic therapeutics here.

Prebiotics

“Prebiotic” is defined as “nondigestible food components that benefi-
cially affect the host by selectively stimulating the growth and/or activ-
ity of 1 or a limited number of bacteria in the colon and thereby
improving host health.” While antimicrobials deplete portions of the
microbiota, prebiotics aim to promote the growth of beneficial organ-
isms such as bifidobacteria and lactobacteria. Typically, prebiotics are
carbohydrates such as oligosaccharides that may be selectively metabo-
lized by constituents of the microbiota. They may not only stimulate
outgrowth of desirable organisms but also may be catabolized to ben-
eficial end products such as SCFA, which may, in turn, be utilized as
energy substrates by the intestinal epithelium. Prebiotic oligosaccharides are naturally found in breast milk and have been used as supplements to human breast milk and formula.

Administration of prebiotics to term infants has demonstrated the expected outgrowth of bacteria; however, clinically significant benefits from prebiotic supplementation have not been clearly established. Treatment of term infants with fructooligosaccharides increases fecal bifidobacteria but without a change in infant growth, despite some infants having increased SCFA in the fecal mass. A systematic review of the topic provided a similar conclusion.

Preterm infants have low to absent levels of bifidobacteria and lactobacilli in their intestinal tracts, despite full breast milk nutrition. Prebiotic supplementation has been proposed as a means to increase these bacterial populations in the preterm infant intestinal tract. Among the proposed benefits may be a decrease in NEC. However, appropriately powered, randomized trials have not been performed to demonstrate the validity of this hypothesis.

**Probiotics**

Probiotics are viable organisms that have health benefits following administration. Nearly all probiotics are isolates from the human microbiota, although they may not necessarily reside in the individual taking them for therapeutic purposes. Alternatively, probiotics may be administered to increase the levels of an organism already present within the microbiota. Generally, probiotics have been administered orally or as vaginal suppositories.

Multiple bacterial and fungal genera and species have been studied for probiotic effects. Common bacterial genera include bifidobacteria, lactobacilli, streptococci, enterococci, and *E. coli*. Fewer nonbacterial organisms, have been studied for probiotic effects. *Saccharomyces bou
dardii* is related to baker’s yeast (*Saccharomyces cerevisiae*) but was isolated for specific beneficial effects.

These probiotic organisms should not be confused with more pathogenic strains within their genera and species. Most probiotics have been isolated on the basis of being associated with healthy states. For instance, bifidobacteria and lactobacilli are common to breast milk and stool among infants with low rates of diarrheal diseases and allergy. With the exception of individuals with significant immunodeficiencies, severely compromised mucosal barriers, and central line catheters, where many of these organisms may adhere to the catheter plastic with otherwise benign transient translocation from the intestinal tract, these bacterial probiotics have proven to be relatively safe even with the administration of billions of colony forming units. The most common adverse events associated with probiotics include abdominal cramping, nausea, fever, soft stools, flatulence, and taste disturbance.

Although bacterial probiotics have been administered widely to humans, evidence for their efficacy is limited to a small number of conditions. Probiotics have consistently shown efficacy for specific conditions, including antibiotic-associated diarrhea, prevention and reduction of atopy in high risk children, and reductions in duration and recurrence of *C. difficile* infection. Trials indicate a reduction in NEC among preterm infants. Probiotics may reduce the risk for respiratory infections and recurrent UTI while reducing the symptoms and frequency of flares in IBD.

Antibiotic-associated diarrhea is reduced in frequency and duration. Metaanalysis indicated a relative risk of antibiotic-associated diarrhea with probiotic administration of 0.58 (95% confidence interval [CI], 0.05-0.68) among combined studies using *Lactobacillus*, *Bifidobacterium*, *Saccharomyces*, *Streptococcus*, *Enterococcus*, and/or *Bacillus*. Administration of combinations of organisms has not generally resulted in greater efficacy.

Metaanalysis specifically for the efficacy of probiotics in decreasing the incidence of CDAD demonstrated moderate evidence for the practice. In an analysis of more than 1,800 trials, including many in the pediatric population, probiotics reduced CDAD by 64% with a relative risk of 0.36 (95% CI, 0.26-0.51). A pediatric subgroup was analyzed across relevant studies, revealing benefit in pediatric patients and a well child subgroup (relative risk 0.37; 95% CI 0.23-0.60). A number of probiotics were used, including different *Lactobacillus* strains and *S. boulardii*.

More than 15 trials have been performed to study the effect of probiotic administration during pregnancy and to infants to prevent atopic dermatitis. Metaanalysis suggests a modest benefit from probiotic administration to prevent the development of atopic dermatitis. Trials have primarily involved the administration of *Lactobacillus rhamnosus*. Studies included administration to the pregnant mother, or the infant, or both. The overall relative risk of 0.79 (95% CI, 0.71-0.88) was generally consistent regardless of the treatment of the mother or child, or both. The duration was generally >6 mo; however, duration did not appear to significantly alter the effect. The RR was similar for the prevention of IgE- and non-IgE–associated atopic dermatitis.

Bibliography is available at Expert Consult.
Bibliography
Immunization is one of the most beneficial and cost-effective disease-prevention measures available. As a result of effective and safe vaccines, smallpox has been eradicated, polio is close to worldwide eradication, and measles and rubella are no longer endemic in the United States, although cases of vaccine-preventable diseases, including measles, rubella, and pertussis, continue to occur in the United States. For most diseases of childhood preventable by vaccination, incidence of most vaccine-preventable diseases of childhood has been reduced by ≥99% from the annual morbidity prior to development of the corresponding vaccine (Table 172-1a), with newer vaccines not achieving quite the same percentage decrease (Table 172-1b). An analysis of effective prevention measures recommended for widespread use by the U.S. Preventive Services Task Force reported that childhood immunization received a perfect score, based on clinically preventable disease burden and cost-effectiveness.

**Immunization** is the process of inducing immunity against a specific disease. Immunity can be induced either passively through administration of antibody-containing preparations or actively by administering a vaccine or toxoid to stimulate the immune system to produce a prolonged humoral and/or cellular immune response. As of 2015, infants, children, and adolescents in the United States routinely are immunized against 16 diseases: diphtheria, tetanus, pertussis, poliomyelitis, *H. influenzae* type b (Hib) disease, hepatitis A, hepatitis B, measles, mumps, rubella, rotavirus, varicella, pneumococcal disease, meningococcal disease, influenza, and human papillomavirus (HPV) infection.

**PASSIVE IMMUNITY**
Passive immunity is achieved by administration of preformed antibodies to induce transient protection against an infectious agent. Products used include:
- Immunoglobulin (Ig) administered intramuscularly (IM)
- Specific or hyperimmune immunoglobulin preparations administered IM
- Intravenous immunoglobulin (IVIG)

- Specific or hyperimmunoglobulin preparations administered IV
- Subcutaneous (SC) human immunoglobulin, which has been licensed to treat patients with primary immunodeficiencies
- Antibodies of animal origin
- Monoclonal antibodies

Passive immunity also can be induced naturally through transplacental transfer of maternal antibodies (IgG) during gestation. Maternally derived transplacental antibodies can provide protection during an infant’s 1st mo of life and longer during breastfeeding. Protection for some diseases can persist for as long as 1 yr after birth, depending on the quantity of antibody transferred and the time until levels fall below those considered protective.

The major indications for passive immunity are to provide protection to immunodeficient children with B-lymphocyte defects who have difficulties making antibodies, for people exposed to infectious diseases or who are at imminent risk of exposure where there is not adequate time for them to develop an active immune response to a vaccine, and for people with an infectious disease as part of specific therapy for that disease (Table 172-2).

Intramuscular Immunoglobulin

Immunoglobulin is a sterile antibody-containing solution, usually derived through cold ethanol fractionation of large pools of human plasma from adults. Antibody concentrations reflect the infectious disease exposure and immunization experience of plasma donors. Immunoglobulin contains 15–18% protein, is predominantly IgG, and is administered IM. IV use of human intramuscular immunoglobulin is contraindicated. Immunoglobulin is not known to transmit infectious agents, including viral hepatitis and HIV.

- The major indications for immunoglobulin are:
  - Replacement therapy for children with antibody deficiency disorders
  - Measles prophylaxis
  - Hepatitis A prophylaxis

For replacement therapy, the usual dose of intramuscular immunoglobulin is 100 mg/kg (equivalent to 0.66 mL/kg) monthly. The usual interval between doses is 2–4 wk depending on trough IgG serum concentrations and clinical response. In practice, IVIG has replaced intramuscular immunoglobulin for replacement therapy. Intramuscular immunoglobulin can be used to prevent or modify measles if administered to susceptible children within 6 days of exposure (usual dose: 0.5 mL/kg of body weight; maximum dose: 15 mL). The recommended dose of IVIG is 400 mL/kg. Data suggest that measles vaccine, if given within 72 hr of measles exposure, will provide protection in some cases. Measles vaccine and immunoglobulin should not be administered at the same time.

Two methods are available for postexposure prophylaxis against hepatitis A. In people 12 mo through 40 yr of age, hepatitis A immunization is preferred over immunoglobulin for postexposure prophylaxis and for protection of people traveling to areas where hepatitis A is endemic. Immunoglobulin may be administered to children <12 mo of age and people >40 yr of age for prophylaxis of hepatitis A and for postexposure prophylaxis for people traveling internationally to hepatitis A–endemic areas (0.06 mL/kg). In children <12 mo of age, adults >40 yr of age, and susceptible children and adults with underlying immunodeficiencies or chronic liver disease, immunoglobulin is preferred over hepatitis A immunization.

The most common adverse reaction to immunoglobulin is pain and discomfort at the injection site and, less commonly, flushing, headache, chills, and nausea. Serious adverse events are rare and include chest pain, dyspnea, anaphylaxis, and systemic collapse. Immunoglobulin should not be administered to people with selective IgA deficiency. Patients with selective IgA deficiency can produce antibodies against the trace amounts of IgA in immunoglobulin preparations and develop reactions after repeat doses. These reactions can include fever, chills,

and a shock-like syndrome. Because these reactions are rare, testing for selective IgA deficiencies is not recommended.

**Intravenous Immunoglobulin**

IVIG is a highly purified preparation of immunoglobulin antibodies prepared from adult plasma donors using alcohol fractionation and is modified to allow IV use. IVIG is more than 95% IgG, and is tested to ensure minimum antibody titers to *Corynebacterium diphtheriae*, hepatitis B virus, measles virus, and poliovirus. Antibody concentrations against other pathogens vary widely among products and even among lots from the same manufacturer. Liquid and lyophilized powder preparations are available. IVIG does not contain thimerosal.

Not all IVIG products are approved by the FDA for all indications. The major **recommended indications** for IVIG for which there is approval by the FDA are:

- Replacement therapy for primary immunodeficiency disorders
- Kawasaki disease to prevent coronary artery abnormalities and shorten the clinical course
- Replacement therapy for prevention of serious bacterial infections in children infected with HIV
- Prevention of serious bacterial infections in people with hypogammaglobulinemia in chronic B-lymphocyte leukemia
- Immune-mediated thrombocytopenia to increase platelet count
- Prophylaxis of infection following bone marrow transplantation

IVIG may be helpful for patients with severe toxic shock syndrome, Guillain-Barré syndrome, and anemia caused by parvovirus B19. IVIG is used for many other conditions based on clinical experience. IVIG may be used for varicella postexposure if varicella-zoster immune globulin is not available.

Reactions to IVIG range from 1-15%. Some of these reactions appear to be related to the rate of infusion and can be mitigated by decreasing the rate. Such reactions include fever, headache, myalgia, chills, nausea, and vomiting. More serious reactions rarely have been reported, including anaphylactoid events, thromboembolic disorders, aseptic meningitis, and renal insufficiency. Renal failure occurs mainly in patients with preexisting renal dysfunction.

**Specific immunoglobulin preparations** are derived from donors with high titers of antibodies to specific agents and designed to provide protection against those agents (see Table 172-2).

**Subcutaneous Immunoglobulin**

Subcutaneous administration of immunoglobulin is safe and effective in children and adults with primary immune deficiency disorders. Smaller doses administered less frequently (weekly) result in less fluctuation of serum IgG concentrations over time. Systemic reactions are less frequent than with IVIG and the most common adverse effects of subcutaneous immunoglobulin are injection-site reactions. There are no data on administration of intramuscular immunoglobulin by the subcutaneous route.

**Hyperimmune Animal Antisera Preparations**

Animal antisera preparations are derived from horses. The immunoglobulin fraction is concentrated using ammonium sulfate, and some products are further treated with enzymes to decrease reactions to foreign proteins. As of 2014, 2 equine antisera preparations are available for humans:

- Diptheria antitoxin, which can be obtained from the CDC (http://www.cdc.gov/diphtheria/dat.html) and is used to treat diphtheria.
- Heptavalent botulinum antitoxin, which is available from the CDC (770-488-7100) for use in adults with botulism. This product contains antitoxin against all 7 (A-G) botulinum toxin types.

Great care must be exercised before administering animal-derived antisera because of the potential for severe allergic reactions. Due caution includes testing for sensitivity before administration; desensitization, if necessary; and treating potential reactions, including febrile events, serum sickness, and anaphylaxis. For **infant botulism**, IVIG (**BabyBIG**), a human-derived antitoxin, is licensed and should be used.

**Monoclonal Antibodies**

Monoclonal antibodies are antibody preparations produced against a single antigen. They are mass-produced from a hybridoma, created by fusing an antibody-producing B lymphocyte with a fast-growing immortal cell such as a cancer cell. **Palivizumab** is a monoclonal antibody that is used for prevention of severe disease from respiratory syncytial virus among children 24 mo of age and younger with chronic lung disease (also called bronchopulmonary dysplasia), with a history of premature birth or with congenital heart lesions or neuromuscular diseases. The American Academy of Pediatrics (AAP) has
developed specific recommendations for use of palivizumab (see Chapter 260). Respiratory syncytial virus–IVIG, a hyperimmunoglobulin formulated for intravenous administration, is no longer produced in the United States. Monoclonal antibodies also are used to prevent transplant rejection and to treat some types of cancer and autoimmune diseases. Monoclonal antibodies against interleukin 2 and tumor necrosis factor α are being used as part of the therapeutic approach to patients with a variety of malignant and autoimmune diseases.

Serious adverse events associated with palivizumab primarily are rare cases of anaphylaxis and hypersensitivity reactions. Adverse reactions to monoclonal antibodies directed at modifying the immune response, such as antibodies against interleukin 2 or tumor necrosis factor, can be more serious, and include cytokine release syndrome, fever, chills, tremors, chest pain, immunosuppression, and infection with various organisms, including mycobacteria.

**ACTIVE IMMUNIZATION**

**Vaccines** are defined as whole or parts of microorganisms administered to prevent an infectious disease. Vaccines can consist of whole inactivated microorganisms (e.g., polio and hepatitis A), parts of the organism (e.g., acellular pertussis, HPV, and hepatitis B), polysaccharide capsules (e.g., pneumococcal and meningococcal polysaccharide vaccines), polysaccharide capsules conjugated to protein carriers (e.g., Hib, pneumococcal, and meningococcal conjugate vaccines), live-attenuated microorganisms (measles, mumps, rubella, varicella, rotavirus, and live-attenuated influenza vaccines), and toxoids (tetanus and diphtheria) (Table 172-3). A toxoid is a modified bacterial toxin that is made nontoxic but is still able to induce an active immune response against the toxin.

Immunizing agents can contain a variety of other constituents besides the immunizing antigen. **Suspending fluids** may be sterile water or saline but could be a complex fluid containing small amounts of proteins or other constituents derived from the biologic system used to grow the immunobiologic. **Preservatives, stabilizers, and antimicrobial agents** are used to inhibit bacterial growth and to prevent degradation of the antigen. Such components can include gelatin, 2-phenoxethanol, and specific antimicrobial agents. Preservatives are added to multidose vials of vaccines, primarily to prevent bacterial contamination on repeated entry of the vial. In the past, many vaccines for children contained thimerosal, a preservative containing ethyl mercury. Beginning in 1999, removal of thimerosal as a preservative from vaccines for children was begun as a precautionary measure in the absence of any data on harm from the preservative. This objective was accomplished by switching to single-dose packaging. Vaccines in the recommended schedule for young children that contain thimerosal as a preservative are some preparations of influenza vaccine. The thimerosal content in U.S.-licensed vaccines currently being manufactured can be found at http://www.fda.gov/BiologicsBloodVaccines/SafetyAvailability/VaccineSafety/ucm096228.htm#pres. **Adjuvants** are used in some vaccines to enhance the immune response. In the United States, the only adjuvants currently licensed by the FDA to be part of vaccines are **aluminum salts and arsenate (AsO₄), an adjuvant** that contains aluminum hydroxide and monophosphoryl lipid A. Vaccines with adjuvants should be injected deeply into muscle masses to avoid local irritation, granuloma formation, and necrosis associated with SC or intracutaneous administration.

Vaccines can induce immunity by stimulating antibody formation, cellular immunity, or both. Protection induced by most vaccines is thought to be mediated primarily by B lymphocytes, which produce antibodies. Such antibodies can inactive toxins, neutralize viruses and prevent their attachment to cellular receptors, facilitate phagocytosis and killing of bacteria, interact with complement to lyse bacteria, and prevent adhesion to mucosal surfaces by interacting with the bacterial cell surface.

Most B-lymphocyte responses require the assistance of CD4 helper T lymphocytes. These T-lymphocyte–dependent responses tend to induce high levels of functional antibody with high avidity, mature over time from primarily an IgM response to a long-term persistent IgG response, and induce immunologic memory that leads to enhanced responses upon boosting. **T-lymphocyte–dependent vaccines**, which include protein moieties, induce good immune responses even in young infants. In contrast, polysaccharide antigens induce B-lymphocyte responses in the absence of T-lymphocyte help. These T-lymphocyte–independent vaccines are associated with poor immune responses in children <2 yr of age, short-term immunity, and absence of an enhanced or booster response on repeat exposure to the antigen. With some polysaccharide vaccines, repeat doses actually are associated with reduced responses, as measured by antibody concentrations, compared to 1st doses (i.e., hyporesponsive). To overcome problems of plain polysaccharide vaccines, polysaccharides have been **conjugated**, or covalently linked, to protein carriers, converting the vaccine to a T-lymphocyte–dependent vaccine. In contrast to plain polysaccharide vaccines, conjugate vaccines induce higher-avidity antibody, immunologic memory leading to booster responses on repeat exposure to the antigen, long-term immunity, and herd protection by decreasing carriage of the organism (Table 172-4). As of 2014 in the United States, there were licensed conjugate vaccines to prevent Hib, pneumococcal, and meningococcal diseases.

Serum antibodies may be detected as soon as 7–10 days after injection of antigen. Early antibodies are usually of the IgM class that can fix complement. IgM antibodies tend to decline as IgG antibodies increase. The IgG antibodies tend to peak approximately 1 mo after vaccination and with most vaccines persist for some time after a primary vaccine course. Secondary or booster responses occur more rapidly and result from rapid proliferation of memory B and T lymphocytes.

Assessment of the immune response to most vaccines is performed by measuring serum antibodies. Although detection of serum antibody at levels considered protective after vaccination can indicate immunity, loss of detectable antibody over time does not necessarily mean susceptibility to disease. Some vaccines induce immunologic memory, leading to a booster or anamnestic response on exposure to the microorganism, with resultant protection from disease. In some instances, cellular immune response is used to evaluate immune status. For some vaccines (e.g., acellular pertussis), there is no accepted serologic correlate of protection.

Live-attenuated vaccines routinely recommended for children and adolescents include measles, mumps, and rubella (MMR); MMR and varicella (MMRV); rotavirus; and varicella. In addition, a cold-adapted, live-attenuated quadrivalent influenza vaccine (LAIV) is available for people 2 through 49 yr of age who do not have conditions that place them at high risk for complications from influenza. Live-attenuated vaccines tend to induce long-term immune responses. They replicate, often similarly to natural infections, until an immune response inhibits reproduction. Most live vaccines are administered in 1 or 2 dose schedules. The purpose of repeat doses, such as a 2nd dose of the MMR or MMRV vaccine, is to induce an initial immune response in people who failed to respond to the 1st dose. Influenza vaccines, including LAIV, are recommended to be administered yearly to provide protection against changes in circulating influenza strains.

The remaining vaccines in the recommended schedule for children and adolescents are inactivated vaccines. Inactivated vaccines tend to require multiple doses to induce an adequate immune response and are more likely to need booster doses to maintain that immunity than live-attenuated vaccines. However, some inactivated vaccines appear to induce long-term immunity, perhaps lifelong immunity, after a primary series, including hepatitis B vaccine and inactivated polio vaccine (IPV).

**VACCINATION SYSTEM IN THE UNITED STATES**

**Vaccine Development**

Basic scientific knowledge about an organism, its pathogenesis, and the immune responses thought to be associated with protection are financed primarily through government sponsorship of academic research and research conducted by private industry (Fig. 172-1). Private industry usually assumes the lead role for guiding potential

*As of January 2015.

Data from Centers for Disease Control and Prevention. U.S. vaccine names. [http://www.cdc.gov/vaccines/about/terms/USvaccines.html](http://www.cdc.gov/vaccines/about/terms/USvaccines.html)
Vaccine candidates through preclinical testing in humans into human clinical trials. There are 3 phases of prelicensure clinical trials: phase I, generally involving <100 participants to gauge safety and dosing; phase II, involving several hundred or more participants to refine safety and dosing; and phase III or pivotal trials that can involve thousands or tens of thousands of participants. Data from phase III trials form the major basis for licensure. Following successful clinical development, the vaccine sponsor applies to the FDA for vaccine licensure. Estimates for the cost of development for each vaccine range to $800 million or more. Following licensure by the FDA, recommendations for use are made by the Advisory Committee on Immunization Practices (ACIP) and postlicensure monitoring is performed on hundreds of thousands to millions of people to monitor vaccine safety and effectiveness.

**Vaccine Production**

Vaccine production is primarily a responsibility of private industry. Many of the vaccines recommended routinely for children are produced by only 1 of the vaccine manufacturers. Only Hib, hepatitis B, HPV, rotavirus, MCV4 (meningococcal conjugate vaccine against serogroups A, C, W135, and Y), diphtheria and tetanus toxoids and acellular pertussis (DTap), and tetanus and diphtheria toxoids and acellular pertussis (Tdap) vaccines for adolescents and adults have multiple manufacturers. IPV as an IPV-only vaccine has only 1 manufacturer, but IPV also is available in combination products DTap–hepatitis B–IPV, DTap-IPV/Hib, and DTap-IPV from different manufacturers. Influenza vaccine for children 2 yr of age or younger is produced by fewer manufacturers (see http://www.cdc.gov/flu/protect/vaccine/vaccines.htm for available influenza vaccines). MMR, MMRV, varicella, pneumococcal conjugate vaccine (13 valent) (PCV13), and tetanus and diphtheria (Td) vaccines also are produced by single manufacturers.

**Vaccine Policy**

There are 2 major committees that make vaccine policy recommendations for children: the Committee on Infectious Diseases (COID) of the AAP (the Red Book Committee) and the ACIP of the CDC. Annually, the AAP, the ACIP, and the American Academy of Family Physicians issue a harmonized childhood and adolescent immunization schedule (http://www.cdc.gov/vaccines/schedules/index.html). The COID consists primarily of academic pediatric infectious disease specialists with liaisons from practicing pediatricians, professional organizations, and government agencies including the FDA, CDC, National Institutes of Health, and National Vaccine Program Office. Recommendations of the COID must be approved by the AAP Board of Directors. The ACIP consists of 15 voting members who are academic infectious disease experts (both children and adults), family physicians, state and local public health officials, nurses, and 1 consumer representative. The ACIP also has representatives from 29 liaison organizations, including major medical societies, professional organizations, managed care, and others, as well as 8 ex officio government entities that deal with vaccines. Only ACIP members vote on vaccine recommendations. Since October 2011, the ACIP has used the Grading of Recommendations Assessment, Development, and Evaluation (GRADE) process to develop evidence-based vaccine recommendations. The ACIP recommendations, available at http://www.cdc.gov/vaccines/acip/recs/index.html, are official only after adoption by the CDC director, which leads to publication in the Morbidity and Mortality Weekly Report (MMWR Morb Mortal Wkly Rep). The AAP recommendations are published in the Red Book and in issues of Pediatrics.

![Figure 172-1 Vaccine development and testing](Modified from Pickering LK, Orenstein WE: Development of pediatric vaccine recommendations and policies, Semin Pediatr Infect Dis 13(3):148–154, 2002.)
Vaccine Financing
Approximately 50% of vaccines routinely administered to children and adolescents <19 yr of age are purchased thorough a contract negotiated by the federal government with licensed vaccine manufacturers. There are 3 major sources of funds that can purchase vaccines through this contract.

The greatest portion comes from the Vaccines for Children (VFC) program (http://www.cdc.gov/vaccines/programs/vfc/index.html), a federal entitlement program established in 1993. The VFC program covers children on Medicaid, children without any insurance (uninsured), and Native Americans and Alaska Natives. In addition, children who have insurance but whose insurance does not cover immunization (underinsured) can be covered through VFC but only if they go to a federally qualified health center (http://www.cms.gov/center/fqhc.asp). In contrast to other public funding sources that require approval of discretionary funding by legislative bodies, VFC funds are immediately available for new recommendations provided the ACIP votes the vaccine and the recommendation for its use into the VFC program, the federal government negotiates a contract, and the Office of Management and Budget apportions funds. The VFC program can provide free vaccines to participating private providers for administration to children eligible for coverage under the program.

The second major federal funding source is the Section 317 Discretionary Federal Grant Program to states and selected localities. These funds must be appropriated annually by Congress, but in contrast to VFC, they have not had eligibility requirements for use. The third major public source of funds is state appropriations. The VFC program itself does not cover vaccine administration costs. Medicaid covers the administration fees for children enrolled in that program. Parents of other children eligible for VFC must pay administration fees out of pocket, although there is a stipulation in the law that no one eligible for the program can be denied vaccines because of inability to pay the administration fee. The Affordable Care Act states that all vaccines recommended by ACIP and included in the immunization schedules must be provided by qualifed insurance programs with no copay and no deductible.

Vaccine Safety Monitoring
Monitoring vaccine safety is the responsibility of the FDA, CDC, and vaccine manufacturers. A critical part of that monitoring depends on reports provided to the Vaccine Adverse Event Reporting System. Adverse events following immunization can be reported by completing a Vaccine Adverse Event Reporting System form that can be obtained from http://www.vaers.hhs.gov, or by calling 1-800-822-7967. Individual Vaccine Adverse Event Reporting System case reports may be helpful in generating hypotheses about whether vaccines are causing certain clinical syndromes, but in general they are not helpful in evaluating the causal role of vaccines in the adverse event. This is because most clinical syndromes that follow vaccination are similar to syndromes that occur in the absence of vaccination, which constitute background rates. For causality assessment, epidemiologic studies are often necessary, comparing the incidence rate of the adverse event after vaccination with the rate in the unvaccinated. A statistically significant higher rate in the vaccinated would be consistent with causation.

The Vaccine Safety Datalink consists of inpatient and outpatient records of some of the largest managed-care organizations in the United States and facilitates causality evaluation. In addition, the clinical immunization safety assessment network has been established to advise primary care physicians on evaluation and management of adverse events (http://www.cdc.gov/vaccinesafety/Activities/CISA.html).

The Institute of Medicine (IOM) has reviewed independently a variety of vaccine safety concerns and published reports (available at http://www.iom.edu/Reports.aspx?Search=vaccine%20safety) summarizing its findings. From 2001 through 2004, the IOM released 8 reports concluding that the body of epidemiologic evidence did not show an association with vaccines and autism.

In 2011, the IOM released a report entitled “Adverse Effects of Vaccines: Evidence and Causality” (http://www.iom.edu/Reports/2011/Adverse-Effects-of-Vaccines-Evidence-and-Causality.aspx), in which the IOM Committee reviewed a list of reported adverse effects associated with 8 vaccines to evaluate the scientific evidence, if any, of an event–vaccine relationship. For the purposes of the report, the committee developed 158 causality conclusions and assigned each relationship between a vaccine and an adverse health problem to 1 of 4 causation categories. The committee concluded that available evidence convincingly supported a causal relationship between MMR, varicella-zoster, influenza, hepatitis B, meningococcal, and tetanus-containing vaccines and anaphylaxis. Additionally, evidence favored rejection of 5 vaccine–adverse event relationships, including MMR vaccine and autism, inactivated influenza vaccines and asthma episodes, as well as Bell palsy, and MMR and DTaP and type 1 diabetes mellitus. For the majority of cases (135 vaccine–adverse event pairs), the evidence was inadequate to accept or reject a causal relationship because of rarity of the events. Overall, the committee concluded that few health problems are caused by or clearly associated with vaccines.

In 2013, the IOM released a report entitled “Childhood Immunization Schedule and Safety: Stakeholder Concerns, Scientific Evidence, and Future Studies” (http://www.iom.edu/Reports/2013/The-Childhood-Immunization-Schedule-and-Safety.aspx). The IOM committee uncovered no evidence of major safety concerns associated with adherence to the recommended childhood immunization schedule. For more information on IOM reports, see http://www.iom.edu/.

The National Vaccine Injury Compensation Program, established in 1988, is designed to compensate people injured by vaccines in the childhood and adolescent immunization schedule. The program is funded through an excise tax of $0.75 per disease prevented per dose. As of 2013, all of the routinely recommended vaccines that protect children against 16 diseases are covered by this program. The National Vaccine Injury Compensation Program was established to provide a no-fault system. There is a table of related injuries and time frames. All people alleging injury from covered vaccines must first file with the program. If the injury meets the requirements of the table, compensation is automatic. If not, the claimant has the responsibility to prove causality. If compensation is accepted, the claimant cannot sue the manufacturer or physician administering the vaccine. If the claimant rejects the judgment of the compensation system, the claimant can enter the tort system, which is uncommon. Information on the National Vaccine Injury Compensation Program is available at http://www.hrsa.gov/vaccinecompensation, or by calling 1-800-338-2382. All physicians administering a vaccine covered by the program are required by law to give the approved Vaccine Information Statement to the child’s parent or guardian at each visit before administering vaccines. Information on the Vaccine Information Statement can be obtained from http://www.cdc.gov/vaccines/hcp/vis/index.html.

Vaccine Delivery
To ensure potency, vaccines should be stored at recommended temperatures before and after reconstitution. A comprehensive resource for providers on vaccine storage and handling recommendations and best practice strategies is available at http://www.cdc.gov/vaccines/recs/storage/default.htm. Expiration dates should be noted, and expired vaccines should be discarded. Lyophilized vaccines often have long shelf lives. However, the shelf life of reconstituted vaccines generally is short, ranging from 30 min for varicella vaccine to 8 hr for MMR vaccine.

All vaccines have a preferred route of administration, which is specified in package inserts and in AAP and ACIP recommendations. Most inactivated vaccines, including DTaP, hepatitis A, hepatitis B, Hib, inactivated influenza vaccine (IIV), HPV, PCV13, MCV4, and Tdap, are administered IM. In contrast, MPV5 and the commonly used live-attenuated vaccines, MMR, MMRV, and varicella, should be dispensed by the SC route and rotavirus vaccine is administered orally. IPV and PPV23 (pneumococcal polysaccharide vaccine) can be given IM or SC. One influenza vaccine, LAIV, is administered intranasally, and another influenza vaccine by the intradermal route. For IM injections, the anterolateral thigh muscle is the preferred site for infants and young children. The recommended needle length varies depending on
age and size: \( \frac{1}{2} \) inch for newborn infants, 1 inch for infants 2 through 12 mo of age, and 1-1.25 inches for older children. For adolescents and adults, the deltoid muscle of the arm is the preferred site for IM administration with needle lengths of 1-1.25 inches depending on the size of the patient. Most IM injections can be made with 23-25 gauge needles. For SC injections, needle lengths generally range from \( \frac{1}{2} \) to \( \frac{3}{8} \) inches with 23-25 gauge needles.

Other areas dealing with various aspects of immunization are important for pediatricians and other healthcare providers. Table 172-5 lists websites providing information in these areas.

**RECOMMENDED IMMUNIZATION SCHEDULE**

All children in the United States should be vaccinated against 16 diseases (Figs. 172-2 and 172-3) (annually updated schedule available at [http://www.cdc.gov/vaccines/schedules/index.html](http://www.cdc.gov/vaccines/schedules/index.html)).

Hepatitis B vaccine is recommended in a 3 dose schedule starting at birth. The birth dose, as well as hepatitis B immunoglobulin, is critical for infants born to mothers who are hepatitis B surface antigen (HBsAg)–positive or whose hepatitis B immune status is unknown, but the recommendation is to administer hepatitis B vaccine to all newborns before hospital discharge.

The DTaP series consists of 5 doses administered at 2, 4, 6, and 15 through 18 mo of age, and 4 through 6 yr of age. The 4th dose of DTaP may be administered as early as 12 mo of age, provided 6 mo has elapsed since the 3rd dose. The 5th (booster) dose of DTaP vaccine is not necessary if the 4th dose was administered at 4 yr of age or older. One dose of an adult preparation of Tdap is recommended for all adolescents at 11 through 12 yr of age. Adolescents 13 through 18 yr of age who missed the 11 through 12 yr of age Tdap booster dose should receive a single dose of Tdap if they have completed the diphtheria, tetanus, and pertussis (DTP)/DTaP series. Tdap may be given at any interval following the last Td. Table 172-6 lists preparations in which DTaP is combined with other vaccines.

There are 3 licensed preparations of single-antigen Hib vaccines. The vaccine conjugated to tetanus toxoid (PRP-T) is given in a 4 dose series at 2, 4, 6, and 12 through 15 mo of age, and the Hib vaccine conjugated to meningococcal outer membrane protein (PRP-OMP) is recommended in a 3 dose series at 2, 4, and 12 through 15 mo of age. The 3rd Hib vaccine is licensed as a booster for children 15 mo through 4 yr of age. There are several vaccines in which Hib is a component, in addition to single-antigen Hib conjugate vaccines (Table 172-7).

Influenza vaccine is recommended for all children beginning at 6 mo of age, with a minimum age of 6 mo for IIVs and 24 mo of age for LAIVs. Various influenza vaccine preparations are FDA licensed for different age groups (see [http://www.cdc.gov/flu/protect/vaccine/vaccines.htm](http://www.cdc.gov/flu/protect/vaccine/vaccines.htm) and [http://aappredbook.aappublications.org/site/news/vaccstatus.xhtml#flu](http://aappredbook.aappublications.org/site/news/vaccstatus.xhtml#flu)). Children 6 mo of age through 8 yr of age being vaccinated for the first time should receive 2 doses at least 4 wk apart. If such children only received a single dose of IIV the prior season, they need 2 doses the following season. For additional guidelines, follow dosing instructions in the influenza statement, which is updated annually by the CDC. Influenza vaccine usually is given in October or November, although there are benefits even when administered as late as February or March because influenza seasons most commonly peak in February. People 9 yr of age and older should receive 1 dose of influenza vaccine annually.

IPV should be administered at 2, 4, and 6 through 18 mo of age with a booster dose at 4 through 6 yr of age. The final dose in the series should be administered on or after 4 yr of age and at least 6 mo after the previous dose. The final dose in the IPV series should be administered at 4 yr of age or older regardless of the number of previous doses, and the minimal interval from dose 3 to dose 4 is 6 mo. For catch-up vaccine recommendations, see the recommended childhood immunization schedule at [http://www.cdc.gov/vaccines/schedules/hcp/imz/catchup.html](http://www.cdc.gov/vaccines/schedules/hcp/imz/catchup.html).

MMR should be administered at 12 through 15 mo of age followed by a 2nd dose at 4 through 6 yr of age. Two doses of varicella vaccine should be given, the 1st at 12 through 18 mo of age and the 2nd at 4 through 6 yr of age. MMR and MMRV preparations are available. The quadrivalent MMRV vaccine is preferred in place of separate MMR and varicella vaccines at the 4 through 6 yr old visit. Because of a slight increase in febrile seizures associated with combined MMRV vaccine compared to the separate products, use of MMRV is not preferred over use of separate MMR and varicella vaccines for the initial dose at 12 through 15 mo of age.

Protection against pneumococcal and meningococcal disease can be provided by either conjugated or polysaccharide vaccines. Conjugated vaccines offer several benefits over polysaccharide vaccines (see [Table 172-4]). PCV13 is recommended as a 4 dose series at 2, 4, 6, and 12 through 15 mo of age. For children 14 through 159 mo of age who have received an age-appropriate series of PCV7, administer a single supplemental dose of PCV13. PPSV23 is recommended for select children with conditions that place them at risk for pneumococcal disease.

A 2 dose series of MCV4 includes a recommended dose for all adolescents at 11 through 12 yr of age and a booster dose at 16 yr of age. If the 1st dose is administered at 13 through 15 yr of age, a booster dose should be administered at 16 through 18 yr of age. No booster dose is needed if the 1st dose is administered at 16 yr of age. In addition, MCV4 should be administered to people 2 mo through 55 yr of age with underlying conditions that place them at high risk of meningococcal disease. People with high-risk conditions should receive 2 doses of MCV4 at 0 and 2 mo followed by booster doses.

Hepatitis A vaccine, licensed for administration to children 12 mo of age and older, is recommended for universal administration to all children at 12 through 23 mo of age and for certain high-risk groups. The 2 doses in the series should be separated by at least 6 mo. Children who have received 1 dose of hepatitis A vaccine before 24 mo of age should receive a 2nd dose 6-18 mo after the 1st dose. For anyone 2 yr of age or older who has not yet received the 2 dose hepatitis A vaccine series, 2 doses of vaccine separated by 6-18 mo may be administered if immunity against hepatitis A infection is desired.

Administer a 3 dose series of HPV vaccine to all adolescents 11 through 12 yr of age. Either HPV4 or HPV2 is recommended in a 3 dose series to females, and only HPV4 in the same schedule is recommended for males. The vaccine series can be started at 9 yr of age. Administer the 2nd dose at 1-2 mo after the 1st dose, and the 3rd dose 6 mo after the 1st dose (at least 24 wk after the 1st dose).

Two rotavirus vaccines are available, RotaTeq (RV5) and Rotarix (RV1). With both vaccines, the 1st dose can be administered as early as 6 wk of age and must be administered by 14 wk 6 days. The final dose in the series must be administered no later than 8 mo of age. The RV5 vaccine is administered in 3 doses at least 4 wk apart. The RV1 vaccine is administered in 2 doses at least 4 wk apart. Immunization should not be initiated for infants 15 wk of age and older as stated in the immunization schedule.

The present schedule, excluding influenza vaccine, can require as many as 34 doses, including 31 that must be administered by injection. Of the doses, 25 are recommended prior to 2 yr of age, including 22 injections. Influenza vaccination, starting at 6 mo of age, can add an additional 20 injections through 18 yr of age. To reduce the injection burdens, several combination vaccines are available (see [Table 172-7]).

The recommended childhood and adolescent immunization schedule establishes a routine adolescent visit at 11 through 12 yr of age. MCV4, a Tdap booster, and HPV vaccine should be administered during this visit. Influenza vaccine should be administered annually. In addition, the 11 through 12 yr old visit is an opportune time to review all of the immunizations the adolescent has received previously, to provide any doses that were missed, and to review other age-appropriate preventive services. The 11 through 12 yr old visit establishes an important platform for incorporating other vaccines. Information on the current status of new vaccine licensure and recommendations for use can be obtained at [http://aappredbook.aappublications.org/site/news/vaccstatus.xhtml](http://aappredbook.aappublications.org/site/news/vaccstatus.xhtml) and [http://www.cdc.gov/](http://www.cdc.gov/)

For children who are at least 1 mo behind in their immunizations, catch-up immunization schedules are available for children 4 mo

</tbody>
</table>
3. Diphtheria and tetanus toxoids and acellular pertussis (DTaP) vaccine (cont’d)

Catch-up vaccination:
- Administer 1 dose of DTaP vaccine to all adolescents aged 11 through 12 years.

For other catch-up guidance, see Figure 172-3.

4. Tetanus and diphtheria toxoids and acellular pertussis (Tdap) vaccine. (Minimum age: 10 years for both Bostrax and Adacel)

Routine vaccination:
- Administer 1 dose of Tdap vaccine to all adolescents aged 11 through 12 years.

For other catch-up guidance, see Figure 172-3.

Catch-up vaccination:
- Persons aged 7 years and older who are not fully immunized with DTaP vaccine should receive Tdap vaccine as 1 dose (preferably the first) in the catch-up series, if additional doses are needed, use Td vaccine.
- For children 7 through 10 years who receive a dose of Tdap as part of the catch-up series, an adolescent Tdap vaccine dose at age 11 through 12 years should be administered.
- Persons aged 11 through 18 years who have not received Tdap vaccine should receive a dose followed by tetanus and diphtheria toxoids (Td) booster doses every 10 years thereafter.
- If inadvertently administered to a child aged 7 through 10 years may count as part of the catch-up series. This dose may count as the adolescent Tdap dose, or the child can later receive a Tdap booster dose at age 11 through 12 years.
- If inadvertently administered to an adolescent aged 11 through 18 years, the dose should be counted as the adolescent Tdap booster.
- For other catch-up guidance, see Figure 172-3.

5. Haemophilus influenzae type b (Hib) conjugate vaccine. (Minimum age: 6 weeks for PRP-T [ActHIB, DTaP-IPV/Hib (Pentacel) and Hib-MenCY (MenHibrix), PRP-OMP [PedvaxHIB or COMVAX], 12 months for PRP-T [Hiberix])

Routine vaccination:
- Administer 2 or 3 dose Hib vaccine primary series and a booster dose (3 or 4) depending on vaccine used in primary series) at age 12 through 15 months to complete a full Hib vaccine series.
- The primary series with ActHIB, MenHibrix, or Pentacel consists of 3 doses and should be administered at 2, 4, and 6 months of age. The primary series with PedvaxHIB or COMVAX consists of 2 doses and should be administered at 2 and 4 months of age; a dose at age 6 months is not indicated.
- One booster dose (3 or 4) depending on vaccine used in primary series) of any Hib vaccine should be administered at age 12 through 15 months. An exception is Hibrix vaccine. Hibrix should only be used for the booster (final) dose in children aged 12 months through 4 years who have received at least 1 prior dose of Hib-containing vaccine.
- For recommendations on the use of MenHibrix in patients at increased risk for meningococcal disease, please refer to the meningococcal vaccine footnotes and also to MMWR February 28, 2014 / 63(RO1)-11, available at http://www.cdc.gov/mmwr/volumes/63/wr/p1.pdf.

Catch-up vaccination:
- If the first dose was administered at ages 12 through 14 months, administer a second (final) dose at least 8 weeks after dose 1, regardless of Hib vaccine used in the primary series.
- If both doses were PRP-OMP (PedvaxHIB or COMVAX), and were administered before the first birthday, a third (and final) dose should be administered at age 1 through 2 years.
- If one dose was PRP-OMP (PedvaxHIB or COMVAX) and one dose was ActHIB, the second dose should be administered at least 4 weeks later and the third (and final) dose should be administered at least 8 weeks after second dose, whichever is later.
- If first dose was administered at age 11 through 12 months, administer the second dose at least 4 weeks later and a third (and final) dose at age 12 through 15 months or 8 weeks after second dose, whichever is later.
- If first dose is administered before the first birthday and second dose administered at younger than 15 months, a third (and final) dose should be given 8 weeks later.
- Unvaccinated children aged 15 months or older, administer only 1 dose.
- For other catch-up guidance, see Figure 172-3. For catch-up guidance related to MenHibrix, please see the meningococcal vaccine footnotes and also MMWR February 28, 2014 / 63(RO1)-11, available at http://www.cdc.gov/mmwr/volumes/63/wr/p1.pdf.

Vaccination of persons with high-risk conditions:
- Children aged 12 through 59 months who are at increased risk for Hib disease, including chemotherapy recipients and those with anatomic or functional asplenia (including sickle cell disease), human immunodeficiency virus (HIV) infection, immunoglobulin deficiency, or early component complement deficiency, who have received either no doses or only 1 dose of Hib vaccine before 12 months of age, should receive 2 additional doses of Hib vaccine 8 weeks apart; children who received 2 or more doses of Hib vaccine before 12 months of age should receive 1 additional dose.
- For patients younger than 5 years of age undergoing chemotherapy or radiation treatment who received a Hib vaccine dose(s) within 14 days of starting therapy or during therapy, repeat the dose(s) at least 3 months following therapy completion.
- Recipients of hematopoietic stem cell transplant (HSCT) should be revaccinated with a 3-dose regimen of Hib vaccine starting 6 to 12 months after successful transplant, regardless of vaccination history; doses should be administered at least 4 weeks apart.
- A single dose of any Hib-containing vaccine should be administered to unimmunized* children and adolescents 15 months of age and older undergoing an elective splenectomy; if possible, vaccine should be administered at least 14 days before the procedure.
- Hib vaccine is not routinely recommended for patients 5 years or older. However, 1 dose of Hib vaccine should be administered to unimmunized* persons 5 years or older who have anatomic or functional asplenia (including sickle cell disease) and unvaccinated persons 5 through 18 years of age with human immunodeficiency virus (HIV) infection.

* Patients who were not vaccinated and booster dose or at least 1 dose of Hib vaccine after 14 months of age are considered unimmunized.

Figure 172-2, cont’d

6. Pneumococcal vaccines. (Minimum age: 6 weeks for PCV13, 2 years for PPSV23)

Routine vaccination with PCV13:
- Administer a 4-dose series of PCV13 vaccine at ages 2, 4, and 6 months and at age 12 through 15 months.
- For children aged 14 through 59 months who have received an age-appropriate series of 7-valent PCV (PCV7), administer a single supplement dose of 13-valent PCV (PCV13).

Catch-up vaccination with PCV13:
- Administer 1 dose of PCV13 to all healthy children aged 24 through 59 months who are not completely vaccinated for their age.
- For other catch-up guidance, see Figure 172-3.

Vaccination of persons with high-risk conditions with PCV13 and PPSV23:
- If recommended, PCV13 doses should be administered prior to PPSV23 vaccination if possible.
- For children 2 through 5 years of age with any of the following conditions: chronic heart disease (particularly cyanotic congenital heart disease and cardiac failure), chronic lung disease (including asthma if treated with high-dose oral corticosteroid therapy), diabetes mellitus, cerebrospinal fluid leak, cochlear implant, sickle cell disease and other hemoglobinopathies, anatomic or functional asplenia, congenital or acquired immunodeficiencies, HIV infection, chronic renal failure, nephrotic syndrome, diseases associated with treatment with immunosuppressive drugs or radiation therapy, including malignant neoplasms, leukemias, lymphomas, and Hodgkin's disease; generalized malignancy; solid organ transplantation; or multiple myeloma:
  1. Administer 1 dose of PCV13 if any incomplete schedule of 3 doses of PCV (PCV7 and/or PCV13) were received previously.
  2. Administer 2 doses of PCV13 at least 8 weeks apart if unvaccinated or any incomplete schedule of fewer than 3 doses of PCV (PCV7 and/or PCV13) were received previously.
  3. Administer supplemental dose of PCV13 if 4 doses of PCV or other age-appropriate complete PCV series was received previously.
  4. The minimum interval between doses of PCV (PCV7 or PCV13) is 8 weeks.
- For children with no history of PPSV23 vaccination, administer PPSV23 at least 8 weeks after the most recent dose of PCV13.
- For children aged 6 through 18 years who have cerebrospinal fluid leak, cochlear implant, sickle cell disease and other hemoglobinopathies; anatomic or functional asplenia; congenital or acquired immunodeficiencies; HIV infection; chronic renal failure; nephrotic syndrome; diseases associated with treatment with immunosuppressive drugs or radiation therapy, including malignant neoplasms, leukemias, lymphomas, and Hodgkin's disease; generalized malignancy; solid organ transplantation; or multiple myeloma:

7. Inactivated poliovirus vaccine (IPV). (Minimum age: 6 weeks)

Routine vaccination:
- Administer a 4-dose series of IPV at ages 2, 4, 6 through 18 months, and 4 through 6 years. The final dose is the series should be administered or after the fourth birthday and at least 6 months after the previous dose.

Catch-up vaccination:
- In the first 6 months of life, minimum age and minimum intervals are only recommended if the person is at risk of imminent exposure to circulating poliovirus (i.e., travel to a polio-endemic region or during an outbreak).
- If 4 or more doses are administered before age 4 years, an additional dose should be administered at age 4 through 6 years and at least 6 months after the previous dose.
- A fourth dose is not necessary if the third dose was administered at age 4 years or older and at least 6 months after the previous dose.
- Fourth OPV and IPV were administered as part of a series; a total of 4 doses should be administered, regardless of the child's current age. IPV is not routinely recommended for U.S. residents aged 18 years or older.
- For other catch-up guidance, see Figure 172-3.

8. Influenza vaccines. (Minimum age: 6 months for inactivated influenza vaccine [IV], 2 years for live, attenuated influenza vaccine [LAIV])

Routine vaccination:
- Administer inactivated influenza vaccine annually to all children beginning at age 6 months. For most healthy, nonpregnant persons aged 2 through 49 years, either LAIV or tIV may be used. However, LAIV should NOT be administered to some persons, including 1) persons who have experienced severe allergic reactions (i.e., anaphylaxis or status asthmaticus) to LAIV, or any of its components, or a history of anaphylaxis or status asthmaticus to one of the following: 2) children 2 through 17 years receiving aspirin or aspirin-containing products, 3) persons who are allergic to eggs, 4) pregnant women, 5) immunosuppressed persons; 6) children 2 through 4 years of age with asthma or who had wheezing in the past 12 months; or 7) persons who have taken inactivated influenza medications in the previous 48 hours. For all other contraindications and precautions to use of LAIV, see MMWR August 15, 2014 / 63(32):691-697 160 pages available at http://www.cdc.gov/mmwr/pdf/rr/rr6332.pdf.
8. Influenza vaccines (cont’d)
For children aged 6 months through 8 years:
- For the 2013-14 season, administer (separated by at least 4 weeks) to children who are receiving influenza vaccine for the first time. Some children in this age group who have been vaccinated previously will also need 2 doses. For additional guidance, follow dosing guidelines in the 2014-15 ACP influenza vaccine recommendations, MMWR August 15, 2014 / 63(32):691-697 [40 pages] available at http://www.cdc.gov/mmwr/pdf/rr/rr6332.pdf.
- For the 2015–16 season, follow dosing guidelines in the 2015 ACP influenza vaccine recommendations.
For persons aged 9 years and older:

9. Measles, mumps, and rubella (MMR) vaccine. (Minimum age: 12 months)
Routine vaccination:
- Administer a 2-dose series of MMR vaccine at ages 12 through 15 months and 4 through 6 years. The second dose may be administered before age 4 years, provided that at least 4 weeks have elapsed since the first dose.
- Administer 1 dose of MMR vaccine to infants aged 6 through 11 months before departure from the United States for international travel. These children should be revaccinated with 2 doses of MMR vaccine, the first at age 12 through 15 months (or 12 months if the child remains in an area where disease risk is high), and the second dose at least 4 weeks later.
- Administer 2 doses of MMR vaccine to children aged 12 months and older before departure from the United States for international travel. The first dose should be administered on or after age 12 months and the second dose at least 4 weeks later.
Catch-up vaccination:
- Ensure that all school-aged children and adolescents have had 2 doses of MMR vaccine; the minimum interval between the 2 doses is 4 weeks.

10. Varicella (VAR) vaccine. (Minimum age: 12 months)
Routine vaccination:
- Administer a 2-dose series of VAR vaccine at ages 12 through 15 months and 4 through 6 years. The second dose may be administered before age 4 years, provided that at least 3 months have elapsed since the first dose. If the second dose was administered at least 4 weeks after the first dose, it can be accepted as valid.
Catch-up vaccination:
- Ensure that all persons aged 7 through 18 years without evidence of immunity (see MMWR 2007 / 56 [No. RR-4]; available at http://www.cdc.gov/mmwr/pdf/rr/rr5604.pdf) have 2 doses of varicella vaccine. For children aged 7 through 12 years, the recommended minimum interval between doses is 3 months if the second dose was administered at least 4 weeks after the first dose, it can be accepted as valid; for persons aged 13 years and older, the minimum interval between doses is 4 weeks.

11. Hepatitis A (HepA) vaccine. (Minimum age: 12 months)
Routine vaccination:
- Initiate the 2-dose HepA vaccine series at 12 through 23 months; separate the 2 doses by 6 to 18 months.
- Children who have received 1 dose of HepA vaccine before age 24 months should receive a second dose 6 to 18 months after the first dose.
- For any person aged 2 years and older who has not already received the HepA vaccine series, 2 doses of HepA vaccine separated by 6 to 18 months may be administered if immunity against Hepatitis A virus infection is desired.
Catch-up vaccination:
- The minimum interval between the two doses is 6 months.
Special populations:
- Administer 2 doses of HepA vaccine at least 6 months apart to previously unvaccinated persons who live in areas where vaccination programs target older children, or who are at increased risk for infection. This includes persons traveling to or working in countries that have high or intermediate endemicity of infection; persons having sex with more than 1 person; users of injection and non-injection Illicit drugs; persons who work with HIV-infected primates or with HIV in a research laboratory; persons with clotting factor disorders; persons with chronic liver disease; and persons who anticipate close personal contact (e.g., household or regular babysitting) with an international adoptee during the first 60 days after arrival in the United States from a country with high or intermediate endemicity. The first dose should be administered at least 8 weeks apart.
- For children who travel to or reside in countries in which meningococcal disease is hyperendemic or epidemic, including countries in the African meningitis belt or the Hajj, administer an age-appropriate formulation and series of MenA or MenC vaccine for protection against serogroups A and C meningococcal disease. Prior receipt of MenB is not sufficient for children traveling to the meningitis belt or the Hajj because it does not contain serogroups A or W.

12. Human papillomavirus (HPV) vaccines. (Minimum age: 9 years for HPV2 [Cervarix] and HPV4 [Gardasil])
Routine vaccination:
- Administer 3 doses of HPV vaccine on a schedule of 0, 1-2, and 6 months to all adolescents aged 11 through 12 years. Either HPV2 or HPV4 may be used for females, and only HPV4 may be used for males.
- The vaccine series may be started at age 9 years.
- Administer the second dose 1 to 2 months after the first dose (minimum interval of 4 weeks); administer the third dose 24 weeks after the first dose and 16 weeks after the second dose (minimum interval of 12 weeks).
Catch-up vaccination:
- Administer the vaccine series to females (either HPV2 or HPV4) and males (HPV4) at age 13 through 18 years if not previously vaccinated.
- Use recommended routine dosing intervals (see Routine vaccination above) for vaccine series catch-up.

13. Meningococcal conjugate vaccines. (Minimum age: 6 weeks for Hib-MenCY MenHibrix, 9 months for MenACY-W-D [Menactra], 2 months for MenACY-W-CRM [Menveo])
Routine vaccination:
- Administer a single dose of Menactra or Menveo vaccine at age 11 through 12 years, with a booster dose at age 16 years.
- Adolescents aged 11 through 18 years with human immunodeficiency virus (HIV) infection should receive a 2-dose primary series of Menactra or Menveo with at least 8 weeks between doses.
- For children aged 2 months through 18 years with high-risk conditions, see below.
Catch-up vaccination:
- Administer Menactra or Menveo vaccine at age 13 through 18 years if not previously vaccinated.
- If the first dose is administered at age 13 through 15 years, a booster dose should be administered at age 16 through 18 years with a minimum interval of at least 8 weeks between doses.
- If the first dose is administered at age 16 years or older, a booster dose is not needed.
- For other catch-up guidance, see Figure 172-3.

Vaccination of persons with high-risk conditions and other persons at increased risk of disease:
- Children with anatomic or functional asplenia (including sickle-cell disease)
  1. Menveo
    o Children who initiate vaccination at 6 weeks through 6 months: Administer doses at 2, 4, 6, and 12 months of age.
    o Unvaccinated children 7 through 23 months: Administer 2 doses, with the second dose at least 12 weeks after the first dose AND after the first birthday.
  2. MenHibrix
    o Children 6 weeks through 18 months: Administer doses at 2, 4, 6, and 12 through 15 months of age.
    o If the first dose of MenHibrix is given at or after 12 months of age, a total of 2 doses should be given at least 8 weeks apart to ensure protection against serogroups C and Y meningococcal disease.
  3. Menactra
    o Children 6 months and older who have not received a complete series: Administer 2 primary doses at least 8 weeks apart.
    o Menactra
    o Children 6 weeks through 18 months: Administer doses at 2, 4, 6, and 12 through 15 months of age.
    o If the first dose of MenHibrix is given at or after 12 months of age, a total of 2 doses should be given at least 8 weeks apart to ensure protection against serogroups C and Y meningococcal disease.
- Children with persistent complement component deficiency
  1. Menveo
    o Children who initiate vaccination at 6 weeks through 6 months: Administer doses at 2, 4, 6, 12 and 18 months of age.
    o Unvaccinated children 7 through 23 months: Administer 2 doses, with the second dose at least 12 weeks after the first dose AND after the first birthday.
  2. MenHibrix
    o Children 6 weeks through 18 months: Administer doses at 2, 4, 6, and 12 through 15 months of age.
    o If the first dose of MenHibrix is given at or after 12 months of age, a total of 2 doses should be given at least 8 weeks apart to ensure protection against serogroups C and Y meningococcal disease.

For other catch-up recommendations for these persons, and complete information on use of meningococcal vaccines, including guidance related to vaccination of persons at increased risk of infection, see MMWR March 22, 2013 / 62(RR02):1-22, available at http://www.cdc.gov/mmwr/pdf/rr/rr6202.pdf.
### FIGURE 172-3. Catch-up immunization schedule for persons aged 4 months through 18 years who start late or who are more than 1 month behind—United States, 2015.

The above recommendations must be read along with the footnotes of this schedule. Use the section appropriate for the child’s age. Always use this table in conjunction with Figure 1 and the footnotes that follow.

#### NOTE: The above recommendations must be read along with the footnotes of this schedule

This table provides catch-up schedules and minimum intervals between doses for children whose vaccinations have been delayed. A vaccine series does not need to be restarted, regardless of the time that has elapsed between doses. Use the section appropriate for the child’s age. Always use this table in conjunction with Figure 1 and the footnotes that follow.

**PCV13** is recommended for all children <5 yr of age who have conditions that place them at high risk for pneumococcal disease. This recommendation includes children with sickle cell disease and other hemoglobinopathies, including hemoglobin SS, hemoglobin S-C, or hemoglobin S-β-thalassemia, or children who are functionally or anatomically asplenic; children with HIV infection; and children who have chronic disease (see Table 172-7). Children at high risk for pneumococcal disease also should receive PPSV23 to provide immunity to serotypes not contained in the 13-valent conjugate vaccine. PPSV23 should be administered on or after the 2nd birthday and should follow completion of the PCV13 series by at least 6-8 wk. Two doses of PPSV23 are recommended, with an interval of 5 yr between doses. Immunization of previously unvaccinated children with high-risk conditions who are >5 yr of age can be performed with either a dose of PCV13 or a dose of PPSV23.

**MCV4** is recommended for people with HIV, children with functional or anatomic asplenia, persistent complement component or properdin deficiencies, and as part of outbreak-control programs.

**VACCINES RECOMMENDED IN SPECIAL CIRCUMSTANCES**

There are 4 vaccines (PCV13, PPSV23, MCV4, and Hib) recommended for children and adolescents at increased risk for complications from vaccine-preventable diseases or children who have an increased risk for exposure to these diseases, who are outside the age groups for which these vaccines are normally recommended (PPSV23 is not routinely recommended for any age group of children and is only used for children with high-risk conditions; see Table 172-7). Specific recommendations for use of these vaccines in children with various underlying conditions can be found in the recommended immunization schedule.

---

vaccine is recommended for children with certain high-risk conditions (see Table 172-7).

A variety of vaccines are available for children who will be traveling to areas of the world where certain infectious diseases are common in addition to vaccines in the recommended childhood and adolescent schedule (Table 172-8). Vaccines for travelers include typhoid fever, hepatitis A, hepatitis B, Japanese encephalitis, MCV4 or MPS4, rabies, and yellow fever, depending on the location and circumstances of travel. Measles is endemic in many parts of the world. Children 6 months of age should receive a dose of MMR before international travel. However, doses of measles vaccine received before 12 mo of age should not be counted in determining compliance with the recommended 2 dose MMR schedule. Additional information on vaccines for international travel can be found at http://wwwnc.cdc.gov/travel/.

Vaccine recommendations for children with immunocompromising conditions, either primary (inherited) or secondary (acquired), vary according to the underlying condition, the degree of immune deficit, the risk for exposure to disease, and the vaccine (Table 172-9). Immunization of children with immunocompromise poses the following potential concerns: the incidence or severity of some vaccine-preventable diseases is higher, and therefore certain vaccines are recommended specifically for certain conditions; vaccines may be less effective during the period of altered immunocompetence and may need to be repeated when immune competence is restored; and because of altered immunocompetence, some children and adolescents may be

| PCV13 (and PPSV23 in certain conditions) | • Immunocompetent children with:  
  • Chronic heart disease (particularly cyanotic congenital heart disease and cardiac failure)  
  • Chronic lung disease (including asthma if treated with high-dose oral corticosteroid therapy)  
  • Diabetes mellitus  
  • Cerebrospinal fluid leaks  
  • Cochlear implant  
  • Anatomic or functional asplenia (including sickle cell disease and other hemoglobinopathies, congenital or acquired asplenia or splenic dysfunction)  
  • Immunocompromising conditions: HIV infection; chronic renal failure and nephrotic syndrome; diseases associated with treatment with immunosuppressive drugs or radiation therapy, including malignant neoplasms, leukemias, lymphomas, and Hodgkin disease or solid organ transplantation; congenital immunodeficiency |
| MCV4 | • Anatomic or functional asplenia (including sickle cell disease)  
  • Persistent complement component deficiency  
  • Residents of or travelers to countries in African meningitis belt or pilgrims on the Haj  
  • During outbreaks caused by a vaccine serogroup |
| Hib | • Anatomic or functional asplenia (including sickle cell disease)  
  • Immunocompromising conditions: HIV disease; immunosuppressive therapy for malignant neoplasms; immunoglobulin deficiency including immunoglobulin G2 subclass deficiency or early complement deficiency; recipients of a hematopoietic stem cell transplant (HSCT) |

at increased risk for an adverse event following receipt of a live viral vaccine. Live-attenuated vaccines generally are contraindicated in immunocompromised people. The exceptions include MMR, which may be given to a child with HIV infection provided the child is asymptomatic or symptomatic without evidence of severe immunosuppression, and varicella vaccine, which may be given to HIV-infected children if the CD4+ lymphocyte count is at least 15%. MMRV is not recommended in these situations.

Altered immunocompetence is considered a precaution for rotavirus; however, the vaccine is contraindicated in children with severe combined immunodeficiency disease. Inactivated vaccines may be administered to immunocompromised children, although, depending on the immune deficit, their effectiveness might not be optimal. Children with complement deficiency disorders may receive all vaccines, including live-attenuated vaccines. In contrast, children with phagocytic disorders may receive both inactivated and live-attenuated viral vaccines but not live-attenuated bacterial vaccines.

Corticosteroids can suppress the immune system. Children receiving corticosteroids (≥22 mg/kg/day or ≥20 mg/day of prednisone or equivalent) for 14 or more days should not receive live vaccines until therapy has been discontinued for at least 1 mo. Children on the same dose levels but for <2 wk may receive live viral vaccines as soon as therapy is discontinued, although some experts would wait 2 wk after therapy has been discontinued. Children receiving lower doses of corticosteroids may be vaccinated while receiving therapy.

Children and adolescents with malignancy, and those who have undergone solid organ or hematopoietic stem cell transplantation and immunosuppressive or radiation therapy, should not receive live virus and live bacterial vaccines depending on their immune status.

Children who have undergone chemotherapy for leukemia may need to be reimmunized with age-appropriate single doses of previously administered vaccines.

**Preterm infants** generally can be vaccinated at the same chronologic age as full-term infants according to the recommended childhood immunization schedule. An exception is the birth dose of hepatitis B vaccine. Infants weighing ≥2 kg and who are stable may receive a birth dose. However, hepatitis B vaccination should be deferred in infants weighing <2 kg at birth until 30 days of age, if born to an HBsAg-negative mother. All preterm, low birthweight infants born to HBsAg-positive mothers should receive hepatitis B immunoglobulin and hepatitis B vaccine within 12 hr of birth. However, such infants should receive an additional 3 doses of vaccine starting at 30 days of age (see Fig. 172-2).

Some children have situations that are not addressed directly in current immunization schedules. There are general rules that physicians can use to guide immunization decisions in some of these instances. In general, vaccines may be given simultaneously on the same day, whether inactivated or live. Different inactivated vaccines can be administered at any interval between doses. However, because of theoretical concerns about viral interference, different live-attenuated vaccines (MMR, varicella, LAIV) if not administered on the same day, should be given at least 1 mo apart. An inactivated and a live vaccine may be spaced at any interval from each other.

Immunoglobulin does not interfere with killed vaccines. However, immunoglobulin can interfere with the immune response to measles vaccine and by inference to varicella vaccine. In general, immunoglobulin, if needed, should be administered at least 2 wk after measles vaccine. Depending on the dose of immunoglobulin received, MMR

*Other vaccines that are universally or routinely recommended should be given if not contraindicated.

\(^v\)OPV is no longer recommended for routine use in the United States.

\(^i\)Live viral vaccines: MMR, MMRV, OPV, LAIV, YF, zoster, rotavirus, and vaccinia (smallpox). Smallpox vaccine is not recommended for children or the general public.

\(^l\)Regarding T-lymphocyte immunodeficiency as a contraindication for rotavirus vaccine, data exist only for SCID.

\(^i\)Pneumococcal vaccine is not indicated for children with chronic granulomatous disease beyond age-based universal recommendations for PCV. Children with chronic granulomatous disease are not at increased risk for pneumococcal disease.

\(^i\)HIV-infected children should receive immunoglobulin after exposure to measles and may receive varicella, measles, and YF vaccine if CD4+ lymphocyte count is greater than 15%. (For YF vaccine, CD4+ T-lymphocyte count between 15% and 24% is a precaution.)

\(^i\)Indicated based on the risk from dialysis-based bloodstream transmission.

BCG, bacille Calmette-Guérin vaccine; Hib, Haemophilus influenzae type b vaccine; HIV/AIDS, human immunodeficiency virus/acquired immunodeficiency syndrome; IVIG, intravenous immunoglobulin; LAIV, live-attenuated influenza vaccine; MMR, measles, mumps, rubella vaccine; MPSV, quadrivalent meningococcal polysaccharide vaccine; OPV, oral poliovirus vaccine (live); PPSV, pneumococcal polysaccharide vaccine; SCID, severe combined immunodeficiency disease; YF, yellow fever.

should be deferred for as long as 3 through 11 mo. Immunoglobulin is not expected to interfere with the immune response to LAIV or rotavirus vaccines.

**PRECAUTIONS AND CONTRAINDICATIONS**

Observation of valid precautions and contraindications is critical to ensure that vaccines are used in the safest manner possible and to obtain optimal immunogenicity. When a child presents for immunization with a clinical condition considered a precaution, the physician must weigh benefits and risks to that individual child. If benefits are judged to outweigh risks, then the vaccine or vaccines in question may be administered. A contraindication means the vaccine should not be administered under any circumstances.

A general contraindication for all vaccines is anaphylactic reaction to a prior dose. Anaphylactic hypersensitivity to vaccine constituents is also a contraindication. However, if a vaccine is essential, there are desensitizing protocols for some vaccines. The major constituents of concern are egg proteins for vaccines grown in eggs; gelatin, a stabilizer in many vaccines; and antimicrobial agents. The measles and mumps components of MMR are grown in chick embryo fibroblast tissue culture. However, the amount of egg protein in MMR is so small as not to require any special procedures before administering vaccine to someone with a history of anaphylaxis following egg ingestion.

Vaccines usually should be deferred in children with moderate to severe acute illnesses, regardless of the presence of fever, until the child recovers. However, children with mild illnesses may be vaccinated. Studies of undervaccinated children have documented opportunities that were missed because mild illness was used as an invalid contraindication. Complete tables of contraindications and contraindication misperceptions can be found at http://www.cdc.gov/vaccines/recs/vac-admin/contraindications.htm.

**IMPROVING IMMUNIZATION COVERAGE**

Standards for child and adolescent immunization practices have been developed to support achievement of high levels of immunization coverage while providing vaccines in a safe and effective manner and educating parents about risks and benefits of vaccines (Table 172-10).

Despite benefits that vaccines have to offer, many children are underimmunized as a result of not receiving recommended vaccines or not receiving them at the recommended ages. Much of the underimmunization problem can be solved through physician actions. Most children have a regular source of healthcare. However, missed opportunities to provide immunizations at healthcare visits include failure to provide all recommended vaccines that could be administered at a single visit during that visit, failure to provide immunizations to children outside of well-child care when the conditions children may have are not contraindications to immunizations, and referral of children to public health clinics because of inability to pay for vaccines. Simultaneous administration of multiple vaccines generally is safe and effective. When the benefits of simultaneous vaccination are explained, many parents prefer such immunization rather than making an extra visit. Providing all needed vaccines simultaneously should be the standard of practice.

Only valid contraindications and precautions to vaccine administration should be observed. Ideally, immunizations should be provided during well-child visits, but using other visits to administer vaccines if there are no contraindications, particularly if a child is behind in the schedule, is important. There is no good evidence that providing immunizations outside of well-child care ultimately decreases well-child visits.

Financial barriers to immunization should be minimized. Participation in the Vaccines for Children program allows physicians to receive vaccines at no cost for their eligible patients, which helps such patients be immunized in their medical home.

Several interventions have been shown to help physicians increase immunization coverage in their practices. Reminder systems for children before an appointment or recall systems for children who fail to keep appointments have repeatedly been demonstrated to improve coverage. Assessment and feedback is also an important intervention. Many physicians overestimate the immunization coverage among patients they serve and thus are not motivated to make any changes in their practices to improve performance. Assessing the immunization coverage of patients served by an individual physician and feedback of results can be a major motivator for improvement. Often public health departments can be contacted to provide the assessments and feedback. Alternatively, physicians can perform some self-assessments. Review of approximately 60 consecutive charts of 2 yr old children may provide a reasonable estimate of practice coverage. Another approach is to have a staff member review the chart of every patient coming in for a visit and placing immunization needs reminders on the chart for the physician. Electronic medical records can be designed to accomplish this goal.

Some parents refuse, delay, or space out immunizations for their children. Pediatricians should try to open a dialog with such parents to understand reasons for refusal and try to work with them to overcome their concerns over time during the course of visits. Discussion should be based on the reason for refusal and the knowledge of the parent. Pediatricians should refer patients to reputable sources

for vaccine information (see Table 172-6) and discuss risks and benefits of vaccines. Provider resources for vaccine conversations with parents are available at http://www.cdc.gov/vaccines/hcp/patient-ed/conversations/index.html. Physician concerns about liability should be addressed by appropriate documentation of discussions in the chart. The Committee on Bioethics of the AAP has published guidelines for dealing with parents' refusal of immunization. Physicians also might wish to consider having parents sign a refusal waiver. A sample of a refusal to vaccinate waiver can be found at http://www2.aap.org/immunization/pediatricians/pdf/refusaltovaccinate.pdf.

Bibliography is available at Expert Consult.

### 172.1 International Immunization Practices

Jean-Marie Okwo-Bele and John David Clemens

Vaccines are used to prevent infectious diseases around the world. However, the types of vaccines in use, the indications and contraindications, and the immunization schedules vary substantially. Most developing countries follow the immunization schedules promulgated by the World Health Organization's Immunization Programme; the latest update is available at http://www.who.int/immunization/policy/Immunization_routine_table2.pdf.

According to this schedule, all children should be vaccinated at birth against tuberculosis with bacille Calmette-Guérin vaccine. Many children also receive a dose of the live-attenuated oral polio vaccine (OPV) at this time. Immunization visits are scheduled for 6, 10, and 14 wk of age when DTP vaccine and OPV are administered. Two doses of measles vaccines are recommended, with the first dose given between 9-12 mo and the second dose between 15-18 mo. Nearly all developing countries have implemented hepatitis B vaccination. Two schedule options may be used, depending on epidemiologic and programmatic considerations. Hepatitis B vaccine can be given at the same time as DTP vaccine doses at 6, 9, and 14 wk of age, often in combination vaccines. To prevent perinatal transmission, the 1st dose should be administered as soon as possible after birth (<24 hr) and at 6 and 14 wk of age. Yellow fever and Japanese encephalitis vaccines are recommended for infants 9 mo of age living in endemic areas. Substantial efforts have been made to incorporate Hib vaccines into all but 3 developing countries that are eligible for support by the GAVI Alliance, often within a DPT-based combination vaccine.

In the past few years, the support from the GAVI Alliance has facilitated the adoption of rotavirus and pneumococcal conjugate vaccines into developing country immunization programs. The increased coverage with these additional vaccines will considerably reduce the global childhood morbidity and mortality caused by pneumonia, meningitis, and diarrheal diseases.

In 1988, the World Health Assembly endorsed the goal of eradicating polio from the world by the end of 2000. Although that goal has not been reached, endemic polio transmission was contained to 3 countries worldwide (Afghanistan, Nigeria, and Pakistan) by the end of 2014. The principal strategy is use of OPV both for routine immunization and in mass campaigns, at least twice per year, during which all children <5 yr of age are targeted for immunization, regardless of prior immunization status. Once termination of wild polio virus transmission is achieved, the goal is to stop use of OPV, which rarely can cause vaccine-associated polio and which is capable of mutating and taking on the phenotypic characteristics of the wild viruses.

Latin American countries have maintained the elimination of indigenous circulation of measles since 2002. The strategy called for attainment of high routine immunization coverage of infants with a dose at 9 mo of age, a 1 time mass campaign targeting all persons 9 mo-14 yr of age regardless of prior immunization status, and follow-up campaigns of children born since the prior campaign, generally every 3-5 yr. While global measles deaths have decreased by 78% worldwide in recent years—from 562,000 deaths in 2000 to 122,000 in 2012—measles is still common in many developing countries, particularly in parts of Africa and Asia. Latin American countries have achieved the elimination of indigenous rubella with strategies consisting of both routine immunization and mass campaigns.

Immunization schedules in the industrialized world are substantially more variable than in the developing world. Immunization recommendations for Canada are developed by the Canadian National Advisory Committee on Immunization but are implemented somewhat differently by each province. The Canadian schedule is similar to the U.S. immunization schedule (http://www.phac-aspc.gc.ca/im/is-cv/index-eng.php), with a few exceptions. A birth dose of hepatitis B vaccine is not specifically recommended as it is in the United States. Conjugate meningococcal vaccine is recommended in a 3 dose series at 2, 4, and 6 mo of age. A single dose is recommended after 12 mo of age if the child has never been immunized or has received <3 doses in infancy. In contrast to the situation in the United States, hepatitis A vaccine is not recommended as a routine pediatric immunization.

There is tremendous variation in vaccines used and the immunization schedules recommended in Europe. European immunization schedules can be reviewed at http://apps.who.int/immunization_monitoring/globalsummary. As an example, the United Kingdom developed an immunization schedule during the late 1980s that includes visits at 2, 3, and 4 mo of age where a combination DTaP-Hib-IPV vaccine is administered. Following evidence that a 3 dose series of Hib vaccine at these ages was insufficient to ensure long-term, high-grade protection, a booster dose was added at 12-13 mo of age. MMR is recommended in a 2 dose schedule at 13 mo and 40 mo of age. During the 2nd MMR visit, a booster of DTaP and IPV is provided. A Td/IPV booster is recommended between 13 and 18 yr of age. PCV13 is recommended at 2, 4, and 12-13 mo of age. The United Kingdom was the first country to use conjugate meningococcal C vaccine (MCV-C) during a massive catch-up campaign for children, adolescents, and young adults. The effectiveness of the vaccine in the 1st yr was 88% or greater, and herd immunity was induced with an approximate two-thirds reduction in the incidence among unvaccinated children. MCV-C is administered at 3, 4, and 12-13 mo of age. In September 2008, HPV vaccine was recommended for girls 12-13 yr old. As of April, 2013, the UK schedule did not include hepatitis B vaccine, varicella vaccine, or influenza vaccine for universal childhood immunization (see http://www.nhs.uk/conditions/vaccinations/pages/vaccination-schedule-age-checklist.aspx).

The Japanese immunization schedule in 2013 is substantially different from that in the United States. The Japanese do not use MMR and rely on individual vaccines for measles and rubella or combined MR. Japanese children also are vaccinated routinely against polio with OPV; against diphtheria, tetanus, and pertussis with DTaP; against Japanese encephalitis; and against tuberculosis with bacille Calmette-Guérin. Adults 65 yr of age and older receive annual influenza vaccinations. A law passed in March 2013 made vaccination of children against Hib, pneumococci, and HPV mandatory.

Some children come to the United States having started or completed international immunization schedules with vaccines produced outside of the United States. In general, doses administered in other countries should be considered valid if administered at the same ages as recommended in the United States. For missing doses, age-inappropriate doses, lost immunization records, or other concerns, pediatricians have 2 options: administer or repeat missing or inappropriate doses or perform serologic tests, and if they are negative, administer vaccines.

Bibliography

Infection prevention and control are playing an ever more important role in pediatric medicine. To be fully effective, such programs require a functional infrastructure that addresses collaboration with the public health system, widespread immunizations, and use of appropriate techniques to prevent transmission of infection within the general population and within healthcare institutions. The national focus upon preventing nosocomial infection is emphasized by the fact that 5 of the 15 elements of the Joint Commission’s 2013 National Patient Safety Goals related to reduction and prevention of healthcare-associated infections (HAIs). Governmental agencies and insurance providers have reduced or eliminated payment to institutions for expenses associated with certain HAIs and a host of national organizations have been established to monitor and report rates of HAI at healthcare facilities. Ratings of healthcare facilities by periodicals such as Parents Magazine and US News and World Report incorporate institutional HAI rates in their reviews and rankings of facilities.

HAIs or nosocomial infections refer to infections acquired during hospitalization or acquired in other healthcare settings, such as nursing homes or ambulatory surgical care centers. An estimated 3-5% of children admitted to hospitals acquire an HAI. HAI rates are highest in patients undergoing invasive procedures. Infections can also be acquired in emergency departments, physicians’ offices, daycare, and long-term care settings. Medical device-associated infections occur in both the home and hospital. Adequate education of home health providers as well as of families is essential to prevent or minimize device-associated infections as ever-greater numbers of children are sent home from the hospital with intravenous catheters and other medical devices in place.

Factors that increase susceptibility to HAIs include host factors, recent invasive procedures, presence of catheters or other devices, prolonged use of antibiotics, contaminated physical environment, and exposure to other patients, visitors, or healthcare providers with active contagious infections or colonized with invasive microorganisms. Host factors increasing the risk for HAIs include anatomic abnormalities (dermal sinuses, cleft palate, obstructive uropathy), abnormal skin, organ dysfunction, malnutrition, and underlying diseases or comorbidities. Invasive procedures can introduce potential pathogens by breaching normal anatomic host barriers. Intravenous and other catheters provide direct access to sterile anatomic sites for usually miniscule volumes of fluid. Intraoperative infections refer to infections acquired during hospitalization or acquired in other healthcare settings, such as nursing homes or ambulatory surgical care centers. Infections can also be acquired in emergency departments, physicians’ offices, daycare, and long-term care settings. Medical device-associated infections occur in both the home and hospital. Adequate education of home health providers as well as of families is essential to prevent or minimize device-associated infections as ever-greater numbers of children are sent home from the hospital with intravenous catheters and other medical devices in place.

The most important tool in any infection control program is good hand hygiene. Although much attention is directed at the type of hand hygiene used, the most important aspect of hand washing is ensuring the hands are dry when entering and exiting the hospital. Studies show that a 15 sec scrub removes the majority of transient flora from the skin, but does not alter hand permanent flora. A variety of hand gels and rubs can be used in place of hand washing. Waterless hand hygiene products increase hand hygiene compliance and save time. These products are the preferred agents for routine hand hygiene when hands are not visibly soiled. These products are effective in killing most microbes but do not remove dirt or debris. However, they are ineffective against C. difficile spores, requiring the use of other cleansing products during hospital C. difficile outbreaks. Hands should be cleaned before and after every patient encounter. In hospital hand washing compliance studies, physicians are usually the least-compliant group studied, and compliance programs must pay special attention to this group of caregivers.

**STANDARD PRECAUTIONS**

Standard precautions, formerly known as universal precautions, are intended to protect healthcare workers from pathogens and should be used whenever there is direct contact with patients. Infected patients are often contagious before symptoms of disease develop. Asymptomatic, infected patients are quite capable of transmitting infectious agents. Standard precautions involve the use of barriers—gloves, gowns, masks, goggles, and face shields—as needed, to prevent transmission of microbes associated with contact with blood and body fluids (Table 173-1).
ISOLATION
Isolation of patients infected with transmissible pathogens decreases the risk of nosocomial transmission of organisms to staff and other patients. The specific type of isolation depends upon the infecting agent and potential route of transmission. Transmission by contact is the most common mode of pathogen transmission and involves direct contact with the patient or contact with a contaminated intermediate object. Contact isolation requires the use of gown and gloves when in contact with the patient or immediate surroundings. Transmission by droplets involves the propulsion of infectious large particles over a short distance (<3 ft), with deposition on another’s mucous membranes or skin. Droplet isolation requires the use of gloves and gowns, as well as masks and eye guards, when closer than 3-6 ft to the patient. Airborne transmission occurs by dissemination of evaporated droplet nuclei (≤5 μm) or dust particles carrying an infectious agent. Airborne isolation requires the use of masks and negative-pressure air-handling systems to prevent spread of the infectious agent. In the case of active pulmonary tuberculosis in older children and adults, severe acute respiratory syndrome, or avian influenza, the use of special high-density masks (N-95) or self-contained breathing systems (PAPR) is recommended. Positive-pressure HEPA-filtered air handling systems are used in some institutions for housing seriously immunocompromised patients.

Standard precautions are indicated for all patients and are appropriate for use in the clinic as well as the hospital. Additionally, for hospitalized patients, further transmission-based precautions are indicated for certain infections (Table 173-2). For contact and droplet isolation, single rooms are preferred but not required. Cohorting children infected with the same pathogen is acceptable, but the etiologic diagnosis should be confirmed by laboratory methods before exposing infected children to one another. Transmission-based isolation precautions should be continued for as long as a patient is considered contagious.

The use of isolation techniques in outpatient settings has not been well studied. Professional offices should establish procedures to ensure that proper cleaning, disinfection, and sterilization methods are employed. Many practices and clinics provide separate waiting areas for acquiring infection or developing adverse outcome following infection.

Contaminated intermediate objects can include many things, from clothing and personal items, to personal protective equipment (PPE), to medical equipment and supplies.

### Table 173-1

<table>
<thead>
<tr>
<th>COMPONENT</th>
<th>RECOMMENDATIONS</th>
</tr>
</thead>
<tbody>
<tr>
<td>Hand hygiene</td>
<td>Before and after each patient contact, regardless of whether gloves are used. After contact with blood, body fluids, secretions, excretions, or contaminated items; immediately after removing gloves; before and after entering patient rooms. Alcohol-containing antiseptic hand rubs preferred except when hands are visibly soiled with blood or other proteinaceous materials or if exposure to spores (e.g., Clostridium difficile, Bacillus anthracis) is likely to have occurred; in those cases, soap and water necessary.</td>
</tr>
<tr>
<td>PERSONAL PROTECTIVE EQUIPMENT</td>
<td></td>
</tr>
<tr>
<td>Gloves</td>
<td>For touching blood, body fluids, secretions, excretions, or contaminated items; for touching mucous membranes and nonintact skin. Employ hand hygiene before and after glove use.</td>
</tr>
<tr>
<td>Gown</td>
<td>During procedures and patient-care activities when contact of clothing or exposed skin with blood/body fluids, secretions, or excretions is anticipated.</td>
</tr>
<tr>
<td>Mask, eye protection (goggles), face shield</td>
<td>During procedures and patient-care activities likely to generate splashes or sprays of blood, body fluids, or secretions, such as suctioning and endotracheal intubation, to protect healthcare personnel. For patient protection, use of a mask by the person inserting an epidural anesthesia needle or performing myelograms when prolonged exposure of the puncture site is likely to occur.</td>
</tr>
<tr>
<td>Soiled patient-care equipment</td>
<td>Handle in a manner that prevents transfer of microorganisms to others and to the environment. Perform hand hygiene.</td>
</tr>
<tr>
<td>ENVIRONMENT</td>
<td></td>
</tr>
<tr>
<td>Environmental control</td>
<td>Develop procedures for routine care, cleaning, and disinfection of environmental surfaces, especially frequently touched surfaces in patient care areas.</td>
</tr>
<tr>
<td>Textiles (linens) and laundry</td>
<td>Handle in a manner that prevents transfer of microorganisms to others and the environment.</td>
</tr>
<tr>
<td>PATIENT CARE</td>
<td></td>
</tr>
<tr>
<td>Injection practices (use of needles and other sharps)</td>
<td>Do not recap, bend, break, or handle used needles; if recapping is required, use a 1-handed scoop technique only. Use needle-free safety devices when available, placing used sharps in puncture-resistant container. Use a sterile, single-use, disposable needle and syringe for each injection. Single-dose medication vials preferred when medications may be administered to more than 1 patient.</td>
</tr>
<tr>
<td>Patient resuscitation</td>
<td>Use mouthpiece, resuscitation bag, or other ventilation devices to prevent contact with mouth and oral secretions.</td>
</tr>
<tr>
<td>Patient placement</td>
<td>Prioritize for single-patient room if patient is at increased risk for transmission, is likely to contaminate the environment, is unable to maintain appropriate hygiene, or is at increased risk for acquiring infection or developing adverse outcome following infection.</td>
</tr>
<tr>
<td>Respiratory hygiene/cough etiquette (source containment of infectious respiratory secretions in symptomatic patients) beginning at the initial point of encounter in such triage or reception areas in an emergency department or physician offices</td>
<td>Instruct symptomatic persons to cover nose/mouth when sneezing or coughing; use tissues with disposal in no-touch receptacles. Employ hand hygiene after soiling of hands with respiratory secretions. Wear surgical mask if tolerated or maintain spatial separation (&gt;3 ft if possible).</td>
</tr>
</tbody>
</table>

Infectious Droplet precautions for 1st 24 etiologic agents that require additional precautions beyond Standard Precautions until they can be ruled out.

Judgment.

Always, hospitals must have systems in place to evaluate patients routinely according to these criteria as part of their preadmission and admission care.

Infection control professionals should modify or adapt this table according to local conditions. To ensure that appropriate empiric precautions are implemented.

*Infection control professionals should modify or adapt this table according to local conditions. To ensure that appropriate empiric precautions are implemented always, hospitals must have systems in place to evaluate patients routinely according to these criteria as part of their preadmission and admission care.

†The organisms listed under the column “Potential Pathogens” are not intended to represent the complete, or even most likely, diagnoses, but rather possible etiologic agents that require additional precautions beyond Standard Precautions until they can be ruled out. These pathogens include enterohemorrhagic Escherichia coli O157:H7, Shigella spp., Hepatitis A virus, noroviruses, rotavirus, Clostridium difficile. AllIR, airborne infection isolation rooms; MRSA, methicillin-resistant Staphylococcus aureus; MSSA, methicillin-susceptible Staphylococcus aureus; SARS, severe acute respiratory syndrome; SARS-CoV, severe acute respiratory syndrome-associated coronavirus; VHF, viral hemorrhagic fever.

for sick and well children. Triage of patients is essential to ensure that contagious children or adults are not present in waiting areas. Outbreaks of measles and varicella in patients within the waiting area have been reported where the air exhaust from examination rooms is allowed to enter the waiting area. Cleaning the clinic environment is important, especially in “high touch” areas. Toys and items that are shared among patients should be cleaned between uses; if feasible, disposable toys should be used. Toys contaminated with blood or body fluids should be autoclaved or discarded.

### ADDITIONAL MEASURES

Other preventive measures include aseptic technique, catheter care, prudent use of antibiotics, isolation of contagious patients, periodic cleaning of the environment, disinfection and sterilization of medical equipment, reporting of infections, safe handling of needles and other sharp instruments, and establishment of employee health services. Aseptic technique must be used for all invasive procedures, including catheter placement and manipulation. The use of barrier techniques at the time of intravenous catheter placement has reduced the rate of catheter-related bloodstream infections by half. Appropriate catheter use also includes limiting the duration and number of catheters employed, scrubbing catheter hubs periodically, and removing catheters as soon as they become unnecessary.

### SURGICAL PROPHYLAXIS

Surgical antibiotic prophylaxis should be employed when there is a high risk of postoperative infection or when the consequences of such infection would be catastrophic. The choice of prophylactic antibiotic depends on the surgical site and type of surgery (Table 173-3). A useful classification of surgical procedures based upon infectious risk recognizes 4 preoperative wound categories: clean wounds, clean-contaminated wounds, contaminated wounds, and dirty and infected wounds. Clinical recommendations regarding antibiotic prophylaxis have been made by the American College of Surgeons, the Surgical Infection Society, and the American Academy of Pediatrics.

Clean wounds are uninfected operative wounds where no inflammation is noted at the operative site and respiratory, alimentary, and genitourinary tracts and the oropharynx are not entered. Such wounds are often the result of nonemergent procedures with primary closure or drained via a closed system. Operative incisional wounds after nonpenetrating trauma are included in this category. For clean wounds, prophylactic antimicrobial therapy is not recommended except in patients at high risk for infection and in circumstances in which the consequences of infection would be potentially life threatening, as with implantation of a foreign body such as a prosthetic heart valve or cerebrospinal fluid shunt, open heart surgery for repair of structural defects, and surgery in immunocompromised patients or small infants. Clean-contaminated wounds are operative wounds in which the respiratory, alimentary, or genitourinary tract is entered under controlled conditions and that do not have unusual bacterial contamination preoperatively. These wounds occur in operations that involve the biliary tract, appendix, vagina, and oropharynx where no evidence of infection or major break in technique is encountered, as well as in urgent or emergency surgery in an otherwise clean procedure. In procedures involving clean-contaminated wounds, the risk for bacterial contamination and infection is variable. Recommendations for pediatric patients derived from data on adults suggest that antibiotic prophylaxis be provided for procedures in children with obstructive jaundice, certain alimentary tract procedures, and urinary tract surgery or instrumentation in the presence of bacteriuria or obstructive uropathy.

Contaminated wounds include open, fresh, and accidental wounds; major breaks in otherwise sterile operative technique; gross spillage from the gastrointestinal tract; penetrating trauma occurring <4 hr earlier; and incisions in which acute nonpurulent inflammation is encountered.

Dirty and infected wounds include penetrating traumatic wounds >4 hr prior to surgery, those with retained devitalized tissue, and those in which clinical infection is apparent or in which the visera have been perforated. In contaminated and dirty or infected wound procedures, antimicrobial therapy is indicated and may need to be continued for several days. In these cases, antibiotic therapy is considered therapeutic rather than truly prophylactic.

</table>

Prophylactic antibiotics should be administered, preferably intrave-
nously, within an hour prior to skin incision, with the intent of having
peak serum concentrations of the drug present in blood and tissues
around the time of incision. Adequate plasma and tissue concentration
of the antibiotic should be maintained until the incision is closed.
Intraoperative antibiotic dosing may be necessary if surgery is pro-
longed and/or the antibiotic being employed has a short intravascular
half-life. Continuation of prophylactic therapy after the procedure is
not recommended. In cases of contaminated surgical sites, antibiotics
are continued as therapy for infection at the site. For patients undergo-
ing colonic procedures, additional oral antibiotics may be employed
and should also be given on the day before surgery.

The selection of antibiotic regimen for prophylaxis is based on the
procedure, the likely contaminating organisms, and antibiotic. Because
of the variety of antibiotics available, many regimens are acceptable
(see Table 173-2).

EMPLOYEE HEALTH
Employee health is important in hospital-based infection control
because employees are at risk for acquiring infection from patients and
infected employees pose a potential risk to patients. This risk is mini-
mized by use of standard precautions and hand hygiene before and
after all patient contacts. Within hospitals, employee health services or
departments of occupational safety and health manage employee
health issues. New employees should be screened for the presence of
infectious diseases. Their immunization history should be noted, and
necessary immunizations should be offered.

All healthcare workers (medical and nonmedical, paid or volunteer,
full time or part time, student or nonstudent, with or without patient
care responsibilities) who work within facilities providing healthcare,
inpatient or outpatient, should be immune to measles, rubella, and
varicella. All workers who are at risk of exposure to blood or body
fluids should be immunized against hepatitis B. In pediatric institu-
tions, employees with patient contact should be urged to receive the
pertussis booster vaccine. Annual influenza immunization is strongly
recommended for all healthcare workers, and institutions are being
ranked publically regarding employee immunization rates as a measure
of quality of care. Many healthcare facilities have now made annual
influenza vaccination mandatory for employees unless there are legiti-
mate medical reasons for nonimmunization. Such a program reduces
staff illness and absenteeism and decreases HAI. Immunizations should
be encouraged and should be provided free of charge whenever pos-
sible to enhance compliance.

All healthcare workers with duties involving face-to-face contact
with patients with suspected or confirmed tuberculosis (including
transport staff) should be included in a tuberculosis screening
program at the time of hiring and may require periodic retesting if
the workplace is determined to be a high-prevalence environment for
tuberculosis. Each medical office and hospital must comply with the
rules developed by the Occupational Safety and Health Administra-
tion. Each office and hospital should have written policies about
exclusion of infected and ill staff from direct patient care. Staff should
be encouraged to not report for work if they are ill. Regular educa-
tional sessions should be performed to ensure that staff are aware of
prevention and control methods and that they adhere to such
policies.

Bibliography is available at Expert Consult.

More than 25 million children <5 yr of age attend a childcare facility. These facilities can include some type of out-of-home care on a routine basis, such as nursery school, preschool, or a full-day program based either in a childcare center or in another person's home. Regardless of the age at entry, children entering daycare are more prone to infections. Exposure to larger groups of children increases a child's probability of getting sick. Childcare facilities can be classified on the basis of size of enrollment, ages of attendees, health status of the children enrolled, and type of setting. As defined in the United States, childcare facilities consist of childcare centers, small and large family childcare homes, and facilities for ill children or for children with special needs. Centers are licensed and regulated by state governments and care for a larger number of children than are cared for in family homes. In contrast, family childcare homes are designated as small (1-6 children) or large (7-12 children), may be full day or part day, and may be designed for either daily or sporadic attendance. Family childcare homes generally are not licensed or registered, depending on state requirements.

Although the majority of children who attend childcare facilities are cared for in childcare home settings, most studies of infectious diseases among children in out-of-home childcare have been conducted among infants (birth to 12 mo of age) and toddlers (13-36 mo of age) who are enrolled in a childcare center. Almost any organism has the potential to be spread and to cause disease in a childcare setting. Epidemiologic studies have established that children in childcare facilities are 2-18 times more likely to acquire a variety of infectious diseases than are children not enrolled in childcare (Table 174-1). Children in childcare facilities are more likely both to receive more courses of antimicrobial agents for longer periods and to acquire antibiotic-resistant organisms. Transmission of infectious agents in group care depends on the age and immune status of the children, season, hygiene practices, crowding, environmental characteristics of the facilities, and characteristics of the pathogen, including its infectivity, survivability in the environment, and virulence. Rates of infection, duration of illness, and risk for hospitalization tend to decrease among children in childcare facilities after the 1st 6 mo of attendance and decline to levels observed among home-bound children after 3 yr of age. Adult caregivers are also at increased risk for acquiring and transmitting infectious diseases, particularly in the 1st yr of contact with children in these settings.

**EPIDEMIOLOGY**

Infectious illnesses among children in childcare and their contacts occur in several different patterns. With many viral infections, children often are infectious 2-3 days before they exhibit symptoms of illness. Respiratory tract infections and diarrhea are the most common diseases associated with childcare. These infections occur in children, childcare staff, and household contacts, and can spread to the community. Respiratory tract pathogens and enteric pathogens can infect both children and adults in these settings but may have varying degrees of impact, depending on the person's underlying health, previous exposures, and age. Infections caused by hepatitis A virus might not be clinically apparent in young children who attend childcare, but can cause major clinical disease among older children and adult contacts, including childcare staff and household contacts. Other diseases, such as otitis media and varicella, usually affect children rather than adults. Some common infections, such as cytomegalovirus (CMV) and parvovirus B19 infections, can have serious consequences for the fetuses.

*Not in the postvaccine era; yes in the prevaccine era.

Use of antimicrobial agents in this population. Pharyngeal carriage of group A streptococcus occurs earlier among children in childcare, although outbreaks of clinical infections with this organism are uncommon. Airborne droplets from the respiratory tract can spread via direct contact with another person’s mucous membranes or by touching surfaces contaminated with secretions. This intimate contact is a routine part of the play and care of young children, regardless of setting. The most common surfaces from which airborne droplets can be spread are the hands; consequently, the most efficient form of infection control in the childcare setting is good hand washing.

**GASTROINTESTINAL TRACT INFECTIONS**

Acute infectious diarrhea is 2-3 times more common among children in childcare than among children cared for in their homes. Outbreaks of diarrhea, which occur frequently in childcare centers, usually are caused by enteric viruses such as rotaviruses, caliciviruses including norovirus, enteric adenoviruses, and astroviruses, or by enteric parasites such as *G. lamblia* or *Cryptosporidium*. The most common enteropathogens, such as rotavirus and *G. lamblia*, are characterized by low infective doses and high rates of asymptomatic excretion among children in childcare. Bacterial enteropathogens such as *Shigella* and *E. coli O157:H7* and, less commonly, *Campylobacter*, *C. difficile*, and *Bacillus cereus* also have caused outbreaks of diarrhea in childcare settings. *Salmonella* rarely is associated with outbreaks of diarrhea in childcare settings, because person-to-person spread of this organism is uncommon. Outbreaks of hepatitis A in children enrolled in childcare facilities have resulted in community-wide outbreaks. Hepatitis A usually is mild or asymptomatic in young children and often is identified only after symptomatic illness becomes apparent among either older children or adult contacts of children in childcare. Enteropathogens and hepatitis A virus are transmitted in childcare facilities by the fecal-oral route and only rarely by contaminated food or water. Children in diapers constitute a high risk for the spread of gastrointestinal infections through the fecal-oral route. Enteric illness and hepatitis A are more common in centers that care for children who are not toilet trained and where proper hygienic practices are not followed.

**SKIN DISEASES**

The most commonly recognized skin infections or infestations in children in childcare are impetigo caused by *S. aureus* or group A streptococcus, pediculosis, scabies, tinea capitis, and tinea corporis. Many of these diseases are spread by contact with infected linens, clothing, hairbrushes, and hats and through direct personal contact; they more often affect children <2 yr of age. The magnitude of these infections and infestations in children in childcare is not known. Parvovirus B19, which causes fifth disease (erythema infectiosum), is spread through the respiratory route, and outbreaks have occurred in childcare centers. The rash of fifth disease is a systemic manifestation of parvovirus B19 infection; the child is no longer contagious once the rash is present (see Chapter 251). The greatest health hazard is for pregnant women and immunocompromised hosts, owing to their respective risks for fetal loss and aplastic crisis.

**INVASIVE ORGANISMS**

Prior to universal immunization, primary *H. influenzae* type b invasive disease was more common among children in childcare, although evidence for increased risk for secondary cases from *H. influenzae* type b in a childcare setting remains less convincing. There is an indication that the risk for primary disease caused by *Neisseria meningitidis* is higher among children in childcare than among children cared for at home. Childcare attendance is associated with nasopharyngeal carriage of penicillin-resistant *S. pneumoniae* and invasive pneumococcal disease, especially among children with a history of recurrent otitis media and use of antibiotics. Secondary spread of *S. pneumoniae* and *N. meningitidis* has been reported, indicating the potential for outbreaks to occur in this setting. Routine use of pneumococcal conjugate vaccine has decreased the incidence of invasive disease and reduced carriage of serotypes of *S. pneumoniae* contained in the vaccine both
infectious diseases

infectious diseases

infectious diseases

herpesviruses

Studies of CMV infection in childcare centers show that as many as 70% of diapered children continuously shed CMV in urine and saliva after they become infected. CMV-infected children often transmit the virus to other children with whom they have contact, as well as to their care providers and their mothers, at a rate of 8-20% per yr. Transmission occurs as a result of contact with either saliva or urine. The overwhelming majority of primary infection with and reactivation of CMV in otherwise healthy children results in asymptomatic shedding of CMV; nonetheless, this shedding can pose a health risk for previously uninfected pregnant childcare providers or immunocompromised persons (see Chapter 255). Varicella often is transmitted in childcare centers, but routine use of varicella vaccine has reduced this risk. Vaccinated children who become infected with varicella often have mild, atypical symptoms and signs of disease that can result in delayed recognition and spread of infection to susceptible contacts. The role of childcare facilities in the spread of herpes simplex virus, especially during episodes of gingivostomatitis, requires further clarification.

blood-borne pathogens

Because it is impossible to identify every child who might have a blood-borne infection such as hepatitis B, C, or D, or HIV, it is critical that standard universal precautions be observed routinely to reduce the risk for transmitting these viruses. Transmission of hepatitis B among children in childcare has been documented in a few rare instances, but the risk for transmission, which already was low, declined with implementation of universal immunization of infants with hepatitis B vaccine. Transmission of hepatitis C or D in childcare settings has not been reported.

Issues about HIV in childcare include the potential risk for HIV transmission within the childcare setting and concerns of opportunistic infections of HIV-infected children. No cases of HIV transmission in out-of-home childcare have been reported. Children with HIV infection enrolled in childcare facilities should be monitored for exposure to infectious diseases, and their health and immune status should be evaluated frequently.

Some infections are spread through contact of contaminated blood with either a mucous membrane or an open wound. Although it is theoretically possible, infection is unlikely to spread via toddler biting in a group setting. Most of these bites do not break the skin, and if a bite does break the skin, the mouth of the biter does not stay on the victim long enough for blood to transfer from the victim to the biter. If there are concerns about transmission of hepatitis B, hepatitis C, or HIV infection, it is recommended to check the status of the biter rather than the bite victim as part of the initial evaluation process.

antibiotic use and bacterial resistance

Antibiotic resistance has become a significant problem in childcare facilities, because the incidence of infection by organisms resistant to frequently used antimicrobial agents has increased dramatically. The estimated annual rate of antibiotic use among children in childcare is 2-4 times higher than among age-matched children cared for at home and the mean duration of antibiotic treatment is 4 times longer among children in childcare. This frequency of antibiotic use combined with the propensity for person-to-person transmission of pathogens in a crowded environment has resulted in an increased prevalence of antibiotic-resistant bacteria in the respiratory and intestinal tracts, including S. pneumoniae, H. influenzae, M. catarrhalis, E. coli O157:H7, and Shigella species. Preliminary data do not demonstrate a difference between methicillin-resistant S. aureus and methicillin-susceptible S. aureus strains in children in childcare.

prevention

Written policies designed to prevent or to control the spread of infectious agents in a childcare center should be available and should be reviewed regularly. It is suggested that all programs use a health consultant to help with development and implementation of infection-control policies. Standards for environmental and personal hygiene should include maintenance of current immunization records for both children and staff; appropriate policies for exclusion of ill children and caretakers; targeting of potentially contaminated areas for frequent cleaning; adherence to appropriate procedures for changing diapers; appropriate handling of food; management of pets; and surveillance for and reporting of communicable diseases. Staff whose primary function is preparing food should not change diapers. Strategies for improving adherence to these standards should be implemented. Appropriate and thorough hand hygiene is the most important factor for reducing infectious diseases in the childcare setting. Children at risk for introducing an infectious disease should not attend childcare until they are no longer contagious (Tables 174-2 and 174-3).

In the United States, there are 15 diseases and organisms for which all children should be immunized unless there are contraindications: diphtheria, pertussis, tetanus, measles, mumps, rubella, polio, hepatitis A and B, varicella, H. influenzae type b, S. pneumoniae, N. meningitidis, and influenza. Rates of immunization among children in licensed childcare facilities are high, in part because of laws in almost all states that require age-appropriate immunizations of children who attend licensed childcare programs. Routine vaccination has had a significant beneficial effect on the health of children in childcare settings. Vaccines against influenza, H. influenzae type b, Rotavirus, varicella, S. pneumoniae, and hepatitis A are of particular benefit to children in childcare centers. Influenza vaccination of younger infants reduces influenza infection and secondary sequelae in both children and the adults who care for them in both their home and in childcare settings. Childcare providers should receive all immunizations that are recommended routinely for adults and have a preemployment health evaluation, including a tuberculin skin test. Local public health agencies are expected to respond to any outbreak of a vaccine-preventable disease in childcare settings through prompt case reporting and investigation.

health authorities should be notified of cases of reportable communicable disease that occur in children or providers in childcare settings.

**STANDARDS**

Every state has specific standards for licensing and reviewing childcare centers and family childcare homes. The American Academy of Pediatrics, the American Public Health Association, and the National Resource Center jointly publish comprehensive health and safety performance standards that can be used by pediatricians and other healthcare professionals to guide decisions about management of infectious diseases and other health-related matters in childcare facilities (available at [http://cfoc.nrckids.org/](http://cfoc.nrckids.org/)). Specific standards set by all states also are available on this website.

*Bibliography is available at Expert Consult.*
Bibliography

Children are traveling internationally with increasing frequency and to more “exotic” destinations that pose unique injury and disease risks. Compared to adults, children are less likely to receive pretravel advice and more likely to be seen by a medical provider or be hospitalized upon return for a travel-related illness. Primary care providers are confronted with the challenge of trying to ensure safe, healthy travel for their patient, whether travel is occurring for purposes of tourism, study abroad, visiting friends and relatives, or volunteerism. Whenever possible, health professionals are encouraged to consult with Travel Medicine specialists, especially when uncertain about pretravel advice, unique travel medicine vaccines (e.g., yellow fever, Japanese encephalitis, typhoid, rabies), and recommendations for malaria medications.

Travel medicine is a unique specialty, and experienced travel medicine practitioners provide specialized guidance on the infectious and noninfectious risks based on age, itinerary, duration, season, purpose of travel, and underlying traveler characteristics (health and vaccination status). A pretravel consultation includes the essential elements of (1) safety and preventive counseling against injuries and diseases; (2) routine, recommended, and required vaccinations, based on individual risk assessment; (3) counseling and medications for self-treatment of traveler’s diarrhea; and (4) when indicated by itinerary, malaria chemoprophylaxis.

In the United States, recommendations and vaccine requirements for travel to different countries are provided by the Centers for Disease Control and Prevention (CDC) and are available online at http://wwwnc.cdc.gov/travel/yellowbook/2014/chapter-3-infectious-diseases-related-to-travel/travel-vaccines-and-malaria-information-by-country. Some travel vaccines and medications may not be recommended based on specifics of travel itinerary, trip duration, or patient characteristics. Alternatively, some vaccinations are not approved for younger children because of lack of data or limited immunologic response, but may still confer potential benefit to the young traveler with off-label vaccine administration. In both scenarios, consultation or referral to a knowledgeable travel medicine practitioner is encouraged, especially if uncertainty exists regarding pretravel recommendations.

**THE PEDIATRIC TRAVEL MEDICINE CONSULTATION**

Parents of traveling children should seek medical consultation at least 4–6 wk before departure to review the travel itinerary, obtain safety and preventive counseling, ensure adequate vaccinations (routine, recommended, and required), receive necessary medications for chronic health conditions, and obtain important medications for self-treatment of traveler’s diarrhea and, when indicated, malaria chemoprophylaxis with counseling. Preparing a child to travel internationally should begin with an emphasis on the positive aspects of the upcoming trip rather than solely focusing on travel risks and diseases. Subsequent advice, vaccinations, and medications should be emphasized as important measures with the provider goal of keeping the child healthy during travel rather than to discourage traveling.
Pediatric Travelers Visiting Friends and Relatives
Compared to most children traveling internationally, the pediatric visiting-friends-and-relatives (VFR) traveler is a vulnerable population uniquely at risk for travel-related illnesses. VFR travelers may include immigrants, refugees, migrants, students, or displaced persons who are traveling back to their country of origin for purposes of visiting friends and relatives. Pediatric VFR travelers are typically children accompanying their parents or family members back to their ancestral country, where relational, social, and cultural connections remain. Compared to tourist travelers, VFR travelers are more likely to travel for longer durations, visit more remote destinations, travel by higher-risk local transportation modes, experience closer contact with the local population, and utilize fewer insect, food, and water precautions. Adult and pediatric VFR travelers are also less likely to perceive a risk of travel-related illnesses, seek pretravel advice, receive travel immunizations, or use effective malaria prophylaxis upon arrival in the destination country. VFR travel comprises 50-84% of imported malaria in children in the United States (i.e., malaria acquired outside the United States), and pediatric VFR travelers are reported to be 4 times more likely to acquire malaria than tourist travelers. Among all travelers, pediatric VFR travelers remain at higher risk for contracting hepatitis A and having symptomatic illness. Several studies suggest that VFR travelers are at disproportionate risk of acquiring typhoid fever and possibly tuberculosis. Providers should inquire if their foreign-born patients will be traveling internationally and seek opportunities to encourage pretravel consultation for VFR travelers.

SAFETY AND PREVENTIVE COUNSELING TOPICS
Health and Evacuation Insurance, Underlying Health Conditions, and Medications
Parents should be made aware that their medical insurance policy might not provide coverage for hospitalizations or medical emergencies in foreign countries and is unlikely to cover the high cost of an emergency medical evacuation. Supplemental travel medical insurance and evacuation insurance may be purchased and are especially recommended for prolonged travel itineraries, for remote destinations, and for children with higher-risk preexistent health conditions going to countries where inpatient care at a level comparable to the traveler’s home country may not be available. A list of medical and evacuation insurance providers can be found at the U.S. Department of State’s International Travel advisory website (http://travel.state.gov/travel/cis_pa_tw/cis/cis_1470.html).

Parents of children with medical conditions should take with them a brief medical summary and a sufficient supply of prescription medications for their children, with bottles that are clearly identified by prescription labels. For children requiring care by specialists, an international directory for that specialty can be consulted. A directory of physicians worldwide who speak English and who have met certain qualifications is available from the International Association for Medical Assistance to Travelers (http://www.iamat.org/index.cfm). If medical care is needed urgently when abroad, sources of information include the American embassy or consulate, hotel managers, travel agents catering to foreign tourists, and missionary hospitals.

A travel health kit consisting of prescription medications and non-prescription items, such as acetaminophen, an antihistamine, oral rehydration solution packets, antibiotic ointment, bandages, insect repellent, and sunscreen, is highly recommended for all children. Children with persistent asthma should have bronchodilators and oral steroids prescribed for treatment of any acute asthma exacerbations encountered during overseas travel. Children with a history of angioedema, anaphylaxis, or severe allergies to food or insects should have an epinephrine autoinjector (EpiPen) and antihistamines available for use during travel.

Parents and family members should be aware of the prevalence of counterfeit medication and lack of quality control of medications in many areas of the world, particularly in low- and middle-income countries. Critical medications, including insulin and newly prescribed antimalarial medications, should be purchased prior to international travel and packed in original prescription containers.

Safety and Injury Prevention
Motor vehicle accidents are a leading cause of traumatic injuries to, hospitalizations of, and deaths of pediatric and adult travelers. Differences in traffic patterns should be emphasized to children, and the use of safety belts should be reinforced. When possible, child safety seats should be taken on the trip. Parents should also be aware of additional risks for small children that may exist overseas, such as open balconies, windows without screens or bars, exposed wires and electrical outlets, paint chips, pest and rodent poison, and stray animals. Water-related activities also are associated with significant injuries in pediatric travelers, and pools and oceanfronts are often unsupervised and without lifeguards at overseas destinations.

Animal Contact
Among travelers, attacks from domestic or stray animals are far more likely to occur than attacks from wild animals. Wounds from animal bites present a risk for bacterial infections, tetanus, and rabies. Dogs are responsible for more than 95% of all rabies transmission in Asia, Africa, and Latin America. Globally, the World Health Organization (WHO) estimates that there are approximately 55,000 human deaths from rabies each year, with the vast majority of cases occurring in South Asia, Southeast Asia, and Africa. Reports of rabies transmission have less commonly occurred following bites from cats and other carnivores, monkeys, and bats. Macaque monkeys, native to Asia and North Africa, can be found in urban centers and tourist sites and pose a risk for rabies and herpes B virus infections following bites and scratches.

Young children are more likely to be bitten and experience more severe facial wounds related to their short stature. As such, they are at higher risk for rabies exposure from dogs and other animals during travel and require greater supervision. Parents should always encourage their children to report bite injuries and to avoid petting, feeding, or handling dogs, monkeys, and stray animals. Before travel, tetanus vaccinations need to be current for all travelers. Children, long-term travelers, expatriates, and all individuals likely to come into contact with animals in a rabies-endemic region (primarily Africa and South and Southeast Asia) should consider preexposure vaccination for rabies before international travel (see “Rabies” below). Bite or scratch wounds should be washed thoroughly and for a prolonged time (15 min) with copious water and soap. Local wound care will substantially reduce the risk of canine and other mammalian rabies transmission. Rabies postexposure vaccination and rabies immunoglobulin should be considered. Antibiotics (amoxicillin–clavulanate) may need to be administered to a child to prevent secondary infections, especially for animal bites involving the hands and head/neck areas.

ROUTINE CHILDHOOD VACCINATIONS REQUIRED FOR PEDIATRIC TRAVEL
Parents should allow 4 or more weeks before departure for optimal administration of vaccines to their children. All children who travel should be immunized according to the routine childhood immunization schedule with all vaccines appropriate for their age. The immunization schedule can be accelerated to maximize protection for traveling children, especially for unvaccinated or incompletely vaccinated children (see Fig. 172–4 in Chapter 172). Routine and catch-up childhood vaccine schedules for healthcare professionals can be found at the CDC website (http://www.cdc.gov/vaccines/schedules/index.html).

Live-attenuated viral vaccines should be administered concurrently or 4 or more weeks apart to minimize immunologic interference. Intramuscular immunoglobulin interferes with the immune response to measles immunization and possibly to varicella immunization. If a child requires measles or varicella immunization, the vaccines should be given either 2 wk before or 3 mo after immunoglobulin administration (longer with higher doses of intravenous immunoglobulin).
Immunoglobulin does not interfere with the immune response to oral typhoid, poliovirus, or yellow fever vaccines.

Vaccine products produced in eggs (yellow fever, influenza) may be associated with hypersensitivity responses, including anaphylaxis in persons with known severe egg sensitivity. Screening by inquiring about adverse effects when eating eggs is a reasonable way to identify those at risk for anaphylaxis from receiving influenza or yellow fever vaccines. Although measles and mumps vaccines are produced in chick embryo cell cultures, children with egg allergy are at very low risk for anaphylaxis with these vaccines.

**Diphtheria-Tetanus-Pertussis**

Children traveling internationally should be fully vaccinated with diphtheria and tetanus toxoids and acellular pertussis (DTaP), having completed the 4th or 5th booster dose by 4-6 yr of age. A single dose of an adolescent/adult preparation of tetanus and diphtheria toxoids and acellular pertussis (Tdap) vaccine is recommended at 11-12 yr of age for those who have completed the recommended primary DTaP (or DTP) series.

Adolescents and adults should receive a single Tdap booster if more than 5 yr have elapsed since the last dose, as a tetanus-containing booster (Td or Tdap) may not be readily available for tetanus-prone wounds during international travel or in remote settings (adventure travel, wilderness).

**Haemophilus influenzae Type B**

*Haemophilus influenzae* type b remains a leading cause of meningitis in children 6 mo to 3 yr of age in many low- and middle-income countries. Before they travel, all unimmunized children <5 yr of age should be vaccinated (see Chapter 172). A single dose of *H. influenzae* type b vaccine should also be administered to unvaccinated or partially vaccinated children who are 5 yr of age or older if they have anatomic or functional asplenia, sickle cell disease, HIV infection, leukemia, malignancy, or other immunocompromising condition. Unvaccinated children who are >5 yr of age do not need vaccination unless they have a high-risk condition.

**Hepatitis A**

Hepatitis A is a routine childhood vaccine in the United States but requires special considerations in the traveling pediatric patient, and protection from hepatitis A in specific children may also involve the provision of immunoglobulin. For this reason, hepatitis A vaccination is covered below in “Specialized Pediatric Travel Vaccinations.”

**Hepatitis B**

Hepatitis B is a travel-associated infection. Hepatitis B is highly prevalent throughout much of the world, including areas of South America, sub-Saharan Africa, eastern and southeastern Asia, and most of the Pacific basin. In certain parts of the world, 8-15% of the population may be chronically infected. Disease can be transmitted via blood transfusions not screened for hepatitis B surface antigen, exposure to unsterilized needles, close contact with local children who have open skin lesions, and sexual exposure. Exposure to hepatitis B is more likely for travelers residing for prolonged periods in endemic areas. Partial protection may be provided by 1 or 2 doses, but ideally 3 doses should be given before travel. For unvaccinated adolescents, the 1st 2 doses are 4 wk apart and are followed by a 3rd dose 8 wk later (at least 16 wk after 1st dose).

All unvaccinated children and adolescents should receive the accelerated hepatitis B vaccine series prior to travel. Because 1 or 2 doses provide some protection, hepatitis B vaccination should be initiated even if the full series cannot be completed before travel.

**Influenza and Avian Influenza**

Influenza remains the most common vaccine-preventable disease occurring among pediatric and adult travelers. The risk for exposure to influenza during international travel varies depending on the time of yr, destination, and intermingling of persons from different parts of the world where influenza may be circulating. In tropical areas, influenza can occur throughout the year, whereas in the temperate regions of the Southern hemisphere, most activity occurs from April through September. In the Northern hemisphere, influenza generally occurs from November through March. Seasonal influenza vaccination is strongly recommended for all pediatric and adolescent travelers who do not have a contraindication or severe egg allergy.

Currently, there is no available vaccine effective against avian influenza, the H5N1 virus, which has become an increasing concern worldwide. However, there are precautions for those traveling to endemic areas, which include parts of Asia, Africa, Eastern Europe, and the Middle East (see the CDC’s website for a detailed list of countries). Because H5N1 influenza is spread through contact with infected birds, these precautions include avoiding direct contact with birds or surfaces with bird droppings, avoiding poultry farms or bird markets, eating only well-cooked bird meat or products, and washing hands frequently. Human-to-human transmission has been reported but is very rare and has not involved spread past 1 person. Oseltamivir is the antiviral of choice to treat avian influenza, because the virus is resistant to amantadine and rimantadine. Oseltamivir is FDA-approved for children 1 yr of age and older but can also be administered for treatment of influenza during infancy with weight-based dosing (http://www.cdc.gov/flu/professionals/antivirals/summary-clinicians.htm).

**Measles-Mumps-Rubella**

Measles is still endemic in many low- and middle-income countries and in some industrialized nations. It remains a leading cause of vaccine-preventable death in much of the world. Vaccine status for measles is important for all traveling children, particularly if they are traveling to low- and middle-income countries or areas with measles outbreaks. Measles vaccine, preferably in combination with mumps and rubella vaccines (MMR), should be given to all children at 12-15 mo of age and at 4-6 yr of age, unless there is a contraindication (see Chapter 172.2). In children traveling internationally, the 2nd vaccination can be given as soon as 4 wk after the 1st, to induce immunity among those children who did not respond to the 1st MMR vaccine.

Children between the ages of 6 and 12 mo who are traveling to the low- and middle-income world should be vaccinated with monovalent measles vaccine. If the monovalent vaccine is unavailable, MMR should be used. Early vaccination (i.e., between 6-12 mo of age) will provide some immunity to measles, but antibody response is not durable or lasting. Any MMR vaccine before 12 mo of age does not count toward the routine vaccination schedule; children vaccinated early for purposes of international travel must be revaccinated on or after their 1st birthday with 2 doses, separated by at least 4 wk. Infants <6 mo of age are generally protected by maternal antibodies and should not receive early MMR vaccination prior to travel.

**Pneumococcal Vaccines**

*Streptococcus pneumoniae* is the leading cause of childhood bacterial pneumonia and is among the leading causes of bacteremia and bacterial meningitis in children in low- and middle-income and industrialized nations. Preparing a child to travel internationally includes routine or catch-up vaccination with 13-valent pneumococcal conjugate vaccine (PCV13) and, for children with certain high-risk conditions, use of 23-valent pneumococcal polysaccharide vaccine (PPSV23). A single dose of PCV13 should be administered to previously unvaccinated children 6-18 yr old with underlying high-risk medical conditions: anatomic or functional asplenia (including sickle cell disease), HIV infection, a congenital immunodeficiency or immunocompromising condition, chronic heart or lung disease, chronic renal failure or nephrotic syndrome, diabetes mellitus, cerebrospinal fluid leak, or cochlear implant. The Advisory Committee on Immunization Practices also recommends that high-risk children age 2 yr and older receive the PPSV23 vaccine 8 or more weeks after their last PCV13 dose. Recommendations of the Advisory Committee on Immunization Practices on prevention of pneumococcal disease among infants and children using PCV13 and PPSV23 can be found at http://www.cdc.gov/vaccines/hcp/acip-recs/vacc-specific/pneumo.html.
**Polio Vaccine**
Poliomyelitis was eradicated from the Western hemisphere in 1991. Polio remains endemic in 3 countries—Afghanistan, Nigeria, and Pakistan—with additional surrounding countries at risk for importation of polio. A number of countries continue to experience periodic outbreaks of importation polio, particularly countries extending from west Africa to the Horn of Africa. The poliovirus vaccination schedule in the United States is now a 4-dose, all-inactivated poliovirus (IPV) regimen (see Chapter 172). Traveling infants should begin IPV series as early as 6 wk of age. For an accelerated dosing schedule for children, see Figure 172-4 in Chapter 172. Length of immunity conferred by IPV immunization is not known; a single booster dose of IPV is therefore recommended for previously vaccinated adolescents and adults traveling to polio-endemic areas if approximately 10 yr has elapsed since they completed their primary series. Oral poliovirus vaccine is no longer available in the United States.

**Varicella**
All children 12 mo of age and older who have no history of varicella vaccination or chickenpox should be vaccinated unless there is a contraindication to vaccination (see Chapter 172). Infants <6 mo of age are generally protected by maternal antibodies. All children now require 2 doses, the 1st at 12 mo of age and the 2nd at 4-6 yr of age. The 2nd dose can be given as soon as 3 mo after the 1st dose. For unvaccinated children 13 yr of age and older, the 1st and 2nd doses can be separated by 4 wk.

**SPECIALIZED PEDIATRIC TRAVEL VACCINATIONS**
Table 175-1 summarizes the dosages and age restrictions of vaccines specifically given to children traveling internationally.

**Cholera**
Cholera is present in many low- and middle-income countries, but the risk for infection among travelers to these countries is extremely low. At present, there is no cholera vaccine available for travelers in the United States, although an effective vaccine is available in other countries. Travelers entering countries reporting cholera outbreaks are at minimal risk of acquiring cholera if they take adequate safe food and water precautions and utilize frequent handwashing. No country or territory currently requires cholera vaccination as a condition for entry.

Hepatitis A Vaccination and Preexposure Immunoglobulin
Hepatitis A virus is endemic in most of the world, and travelers are at risk, even if their travel is restricted to the usual tourist routes. Hepatitis A infection can occur as a result of eating shellfish harvested from sewage-contaminated waters, eating unwashed vegetables or fruits, or eating food prepared by an asymptomatic carrier of hepatitis A virus. Young children infected with hepatitis A are often asymptomatic but can transmit infection to older children and adults, who are more likely to develop clinical hepatitis. Few areas carry no risk of this infection, and therefore immunization is recommended for all travelers. Hepatitis A vaccine is recommended in the United States for universal immunization of all children 12 mo of age or older, administered as 2 doses 6 mo apart. A single dose of hepatitis A vaccine given to travelers will provide adequate protection in most instances. Protective immunity develops within 2 wk after the initial vaccine dose. A combined 3 dose hepatitis A and hepatitis B vaccine (Twinrix, GlaxoSmithKline) is available in the United States but is licensed for use only in adolescents >18 yr of age. Pediatric combination hepatitis A–hepatitis B vaccine (Twinrix-Junior, GlaxoSmithKline) is licensed for use in children 1-18 yr in Canada and Europe.

Children <1 yr of age are at lower risk of clinical hepatitis A infection, especially if they are breastfed or residing in areas with safe water for formula reconstitution. Some experts recommend use of preexposure intramuscular immunoglobulin for children <12 mo who are traveling internationally to higher-risk destinations, particularly low-income destinations or regions where hygienic or sanitary conditions are limited. However, administration of immunoglobulin diminishes the immunogenicity of live-virus vaccines, in particular measles vaccine, that may be needed for infant travelers. Vaccination against measles should occur 2 or more weeks prior to any immunoglobulin administration, and a 3 mo interval is suggested between immunoglobulin administration and subsequent measles immunization.

Providers should be aware that infant travelers 6 mo of age or older who are being considered for preexposure immunoglobulin may also need measles (MMR) vaccination, as measles-endemic countries frequently overlap with higher-risk travel destinations for hepatitis A virus infection. For this reason, and on the basis of vaccine safety data, many travel medicine experts recommend immunization with hepatitis A vaccine rather than administration of intramuscular immunoglobulin to infants 6-11 mo of age who will be traveling to a hepatitis A virus–endemic area. Several studies demonstrate that infants as young as 6 mo old will develop antibodies following hepatitis A vaccine, especially if there are no interfering maternal antibodies from prior maternal vaccination or disease. There is potential for a more durable immune response to the hepatitis A vaccination especially in later infancy, when potential interfering maternal antibody concentrations are lower. If early hepatitis A vaccination is given rather than immunoglobulin to infant travelers (age 6-11 mo), it should not count toward the routine 2 dose vaccine series. Similar to MMR vaccination, an informed decision should be made, with the parents balancing the risk of travel-associated disease and vaccine adverse events with the potential protective benefit to the traveling infant.

Japanese Encephalitis
Japanese encephalitis is a disease transmitted by mosquitoes in many areas of Asia, especially in rural farming areas. Although it is a leading cause of vaccine-preventable encephalitis in children in many Asian countries and parts of western Pacific countries, the risk of disease to nonimmune travelers is low. A map showing where Japanese encephalitis transmission occurs can be found at http://wwwn.cdc.gov/travel/yellowbook/2012/chapter-3-infectious-diseases-related-to-travel/japanese-encephalitis#2473.

Most human infections with Japanese encephalitis virus are asymptomatic, and <1% of individuals develop clinical disease. With symptomatic disease, the fatality rate is 20-30% and the incidence of neurologic or psychiatric sequelae in survivors is 30-50%. The risk of Japanese encephalitis disease for pediatric travelers is unknown, but among all travelers, it is estimated to be less than 1 case per 1 million travelers to Asia. Risk of Japanese encephalitis neurologic disease following mosquito-bite transmission is thought to be higher in children than adults. The disease occurs primarily from June to September in temperate zones and throughout the entire year in tropical zones. Vaccination is recommended for travelers planning visits of longer than 1 mo to rural areas of Asia, where the disease is endemic, especially areas of rice or pig farming. Vaccination is recommended for shorter visits to such areas if the traveler will often be outdoors (e.g., camping or hiking). Risk for infection can be greatly reduced by following the standard precautions to avoid mosquito bites.

The inactivated Vero-cell culture-derived Japanese encephalitis vaccine (Ixiaro) has replaced the older inactivated mouse-brain-derived vaccine (JE-VAX), which is no longer manufactured. Japanese encephalitis (Ixiaro) vaccine efficacy is >95% in adults who receive 2 doses administered 28 days apart. The licensed range for Japanese encephalitis vaccine (Ixiaro) has been extended to include children as young as age 2 mo, with a dose administered on days 0 and 28.

Meningococcal Vaccines
There are currently 2 forms of meningococcal vaccine available in the United States: a quadrivalent polysaccharide A/C/Y/W-135 vaccine (Menomune) and 2 quadrivalent conjugate A/C/Y/W-135 vaccines (Menactra, Menveo). A single-dose conjugate quadrivalent A/C/Y/W-135 vaccine, Nimenrix (manufactured by GlaxoSmithKline), is licensed in Canada and Europe for individuals from 12 mo-55 yr of age.

Children traveling to those equatorial countries in sub-Saharan Africa where the incidence of meningococcal disease is highest should receive a Neisseria meningitidis vaccine, especially if travel is prolonged or occurs during the dry season of December to June. Risk is greatest in the “meningitis belt” of sub-Saharan Africa (see the map at http://wwwn.cdc.gov/travel/yellowbook/2012/chapter-3-infectious-diseases-related-to-travel/meningococcal-disease), with rates of meningococcal disease in endemic regions reaching up to 1,000 cases per 100,000 population per year. Children 9-23 mo of age who are traveling to these equatorial African countries where meningococcal disease is hyperendemic or epidemic should receive a 2 dose series of Menactra brand MCV4, 8-12 wk apart. Conjugate vaccine is preferred in children over the less-effective polysaccharide vaccine (Menomune). Booster doses of conjugate A/C/Y/W-135 should occur every 3-5 yr for travelers returning to endemic areas, depending on age of pediatric traveler. Providers may also wish to consider meningococcal vaccination for other pediatric travelers, especially if there is remote or rural travel to low-income countries with limited healthcare access, as meningococcal outbreaks can occur anywhere in the world. Proof of receipt of quadrivalent meningococcal vaccination is also necessary for individuals traveling to Mecca, Saudi Arabia, for the annual Hajj or Umrah pilgrimages.

Serogroups A and C are most commonly associated with epidemics of meningitis in sub-Saharan Africa, especially in the “meningitis belt” of equatorial Africa during the dry season mo (December to June). Serogroups Y and W-135 have also been found in meningococcal outbreaks. Serogroup B, currently not included in any licensed meningococcal vaccine in the United States, is associated with more sporadic cases of invasive meningococcal disease in industrialized countries, including the United States. Additional vaccine information on meningococcal vaccination regimens and booster intervals can be found at the CDC website (http://www.cdc.gov/vaccines/vpd-vac/mening/#reccs).

Rabies
Rabies is endemic in many countries in Africa, Asia, and Central and South America. Children are at particular risk because they are less likely to report bites and because facial bites are more common in children. Rabies has the potential for an extended latency period (months) and is uniformly fatal once the clinical symptoms emerge. Preexposure prophylaxis is recommended for ambulatory children with extended travel to high-risk regions, especially expatriate children and younger children traveling to or living in rural areas where enzootic dog rabies is endemic. Rabies preexposure vaccination should also
be considered for adventure travelers (hikers, bikers), individuals likely to come into contact with rabies vectors (i.e., students working with animal or bat conservation), or travelers with itineraries to rabies-endemic regions where timely, effective postexposure prophylaxis might not be available following an animal bite. Most animal bites in a rabies-endemic area should be considered a medical emergency, especially bites from stray dogs, other carnivores, and bats. Immediate wound care washing should be followed by prompt administration of appropriate postexposure rabies prophylaxis at a medical facility. Postexposure prophylaxis is required even for persons who received preexposure vaccination. Algorithms for pre- and postexposure vaccination are the same regardless of patient age.

Numerous rabies vaccine formulations exist around the world. In the United States, 2 rabies vaccines are available: human diploid cell vaccine (HDCV; Imovax, Sanofi Pasteur, SA) and purified chick embryo cell (PCEC; RabAvert, Novartis) vaccine. Preexposure prophylaxis is given either intramuscularly (HDCV or PCEC) as 3 doses (1 mL) on days 0, 7, and 21 or 28. Postexposure prophylaxis is given as 4 doses (1 mL) of HDCV or PCEC vaccine intramuscularly on days 0, 3, 7, and 14 if previously unvaccinated and 2 doses (1 mL) intramuscularly on days 0 and 3 if previously vaccinated. Previously unvaccinated persons should also receive rabies immunoglobulin (RIG, 20 IU/kg), with as much of the dose as possible infiltrated around the wound site at the time of initial postexposure prophylaxis. Previously vaccinated persons should not receive RIG. Unpurified or purified equine RIG preparations are still used in some low- and middle-income countries and are associated with a higher risk for severe reactions, including serum sickness and anaphylaxis. Purified cell culture–derived vaccines are also not always available abroad; travelers should be aware that any rabies vaccines derived from neural tissue carry an increased risk for adverse reactions, often with neurologic sequelae. If rabies prophylaxis is initiated abroad, neutralizing titers should be checked on return and immunization completed with a cell culture–derived vaccine. If rabies prophylaxis cannot be provided abroad, children with high-risk bites (e.g., stray dog) should be emer-
gently transported to a site where they can receive prophylaxis, as the vaccinations should be started as soon as possible after the bite and ideally within 24 hr. Infants and young children respond well to rabies vaccine, and both pre- and postexposure vaccinations can be given at any age, using the same dose and schedule as adults. Individual travel-
ners simultaneously receiving mefloquine or chloroquine may have limited immune reactions to intradermal rabies vaccine and should be vaccinated intramuscularly.

**Tuberculosis**

The risk for tuberculosis in the typical traveler is low. Pre- and post-travel testing for tuberculosis is controversial, and should be done on an individualized basis depending on the itinerary, duration, and activities (i.e., working in a hospital setting). Immunization with bacillus Calmette-Güerin is even more controversial. It has variable efficacy in reducing severe tuberculosis disease in infants and young children, is not available in the United States, and is generally not recommended for pediatric travelers. Infection with *Mycobacterium bovis* can be prevented through avoidance of unpasteurized dairy products.

**Typhoid**

*Salmonella typhi* infection, or typhoid fever, is common in many low-and middle-income countries in Asia, Africa, and Latin America (see Chapter 198). Typhoid vaccination is recommended for most children 2 yr of age or older who are traveling to the Indian subcontinent, as the incidence of typhoid is 10-100 times higher for travelers to the Indian subcontinent than all other travel destinations. Vaccination should be strongly considered for other travelers to low- and middle-income countries, particularly if they are visiting friends and relatives, lack access to reliable clean water and food, are traveling for a pro-
longed duration, or are adventurous eaters.

Two typhoid vaccines, the intramuscular Vi-polysaccharide vaccine and oral Ty21a strain live-attenuated vaccine, are recommended for use in children in the United States. Both produce a protective response in 50-80% of recipients. Neither vaccination offers meaningful protec-
tion against *Salmonella paratyphi*, another cause of enteric fever. Travel-
ers who have had prior diagnoses of “typhoid fever” should still receive vaccination, as past infection does not confer long-term immunity.

The intramuscular Vi-polysaccharide vaccine is licensed for use in children 2 yr of age and older. It can be given any time before depar-
ture, but it should ideally be administered 2 wk before travel, with a booster needed 2-3 yr later. The oral Ty21a vaccine can only be used in children 6 yr of age or older and is given in 4 doses over a 1 wk period. Enteric-coated capsules are to be swallowed with a cool or room-temperature drink, at least 1 hr before a meal, every other day until the 4 doses are completed. Oral typhoid capsules must remain refrigerated (not frozen). Capsules should never be broken open, as vaccine efficacy is dependent on capsules being swallowed whole in order to get past the acidic stomach contents. The oral vaccine is associ-
ated with an immune response lasting 5-7 yr (depending on national labeling). Antibiotics inhibit the immune response to the oral Ty21a vaccine; the vaccine should not be given within 72 hr of antibiotic treatment, and antibiotics should be avoided until 7 days after complet-
ing the vaccine series. Studies demonstrate that mefloquine, chloro-
quine, and atovaquone-proguanil can be given concurrently with the oral Ty21a vaccine without affecting the immunogenicity of the vaccine. Oral Ty21a vaccine should not be given to immunocompro-
mised children; these children should receive the intramuscular Vi-polysaccharide vaccine.

**Yellow Fever**

Yellow fever (see Chapter 270) is a mosquito-borne viral illness resem-
bling other viral hemorrhagic fevers (see Chapter 271) but with more prominent hepatic involvement. Yellow fever is present in tropical areas of South America and Africa.

Yellow fever vaccination is indicated in children >9 mo of age travel-
ing to an endemic area. Many countries require yellow fever vaccina-
tion by law for travelers arriving from endemic areas, and some African countries require evidence of vaccination from all entering travelers. Current recommendations can be obtained by contacting state or local health departments or the Division of Vector-Borne Infectious Dis-
eses of the CDC (telephone: 404-332-4555; or website: http://wwwncc .cdc.gov/travel/yellowbook/2014/chapter-3-infectious-diseases-related-to-travel/yellow-fever). Most countries accept a medical waiver for children who are too young to be vaccinated (<6 mo of age) and for persons with a contraindication to vaccination. Children with asymptomatic HIV infection may be vaccinated if exposure to yellow fever virus cannot be avoided.

Yellow fever vaccine (0.5 mL SC), a live-attenuated vaccine (17D strain) developed in chick embryos, is safe and highly effective in children >9 mo of age, but in young infants it is associated with a markedly increased risk for vaccine-associated encephalitis (0.5-
4/1,000) and other severe reactions. Yellow fever vaccine should never be given to infants <6 mo of age; infants 6-8 mo of age should be vac-
cinated only in consultation with the CDC or a travel medicine expert to assess the current epidemiology, travel itinerary and duration, and whether the yellow fever virus exposure is greater than vaccine risks. In children >9 mo, adverse effects are rare, although vaccine-associated neurotropic and viscerotropic disease associated with the vaccine have been reported. The risk of these reactions is higher in those with thymus disease, altered immune status, age >60 yr, or multiple sclerosis and in infants <9 mo of age (neurotropic disease). Yellow fever vacci-
nation is generally contraindicated in pregnancy and for nursing mothers, unless extended travel to a yellow fever–endemic area is unavoidable.

Children with immunodeficiency or an immunosuppressed state, a thymic disorder or dysfunction (i.e., DiGeorge syndrome), or a history of anaphylactic reactions to eggs should not receive yellow fever vaccine. Long-lived immunity develops with this vaccine, perhaps even lasting for a lifetime; however, international travel certificates require proof of immunization within 10 yr.
Traveler's Diarrhea

Ingestion of contaminated food or water makes travel-associated diarrhea the most common health complaint among international travelers. Traveler's diarrhea, characterized by a 2-fold or greater increase in the frequency of unformed bowel movements, occurs in as many as 40% of all travelers overseas (see Chapter 340.1). Children, especially those <3 yr of age, have a higher incidence of diarrhea, more-severe symptoms, and more-prolonged symptoms than adults, with a reported attack rate of 60% for those <3 yr of age in 1 study.

An important risk factor for traveler's diarrhea is the country of destination. High-risk areas (attack rates of 25-50%) include low- and middle-income countries of Latin America, Africa, the Middle East, and Asia. Intermediate risk occurs in the Mediterranean, China, and Israel. Low-risk areas include North America, Northern Europe, Australia, and New Zealand. Fecal-oral diarrheal pathogens that children acquire during travel are similar to those acquired by adults and include enterotoxigenic and enteraggregative Escherichia coli, Campylobacter, Salmonella (nontyphoidal serotypes predominate), and Shigella species. Enteric protozoa are a much less common cause of traveler's diarrhea than bacterial pathogens—G. lamblia is the most likely protozoal cause of persistent diarrhea. Less-common travel-associated protozoa include Cryptosporidium species, E. histolytica, and Cyclospora. Viral infections, particularly rotavirus infections, may also cause travel-associated diarrhea in children. Clinicians should be aware that not all diarrheal illness in children is food borne or waterborne—febrile children with malaria may also present with vomiting and/or nonbloody diarrhea and may be misdiagnosed as having traveler's diarrhea.

Guidance on Prevention of Traveler's Diarrhea

Food and water hygiene remain important measures to reduce the incidence of traveler's diarrhea in children. However, creating long lists of foods to avoid or offering the popular, simple advice of “Boil it, peel it, cook it, or forget it!” is generally an ineffective method of reducing traveler's diarrhea. Most studies show that these kinds of dietary directives are difficult to keep and may have little impact on the incidence of traveler's diarrhea. In adult studies, the risk of developing traveler's diarrhea appears to be more associated with where you eat rather than what you eat. Eating in a relative’s or friend's home is generally safer than eating in a restaurant, where restaurant kitchen hygiene and proper refrigeration may be lacking and employee handwashing may be sporadic.

In general, travel medicine providers can provide some common sense food and water advice to family travelers. Boiled or bottled water, hot beverages, and canned or bottled beverages are generally safe to consume. Ice should be avoided. In low- and middle-income countries, tap water is generally unsafe for drinking or brushing teeth. Boiling water for 1 min or longer (or 3 min at altitudes >2000 m) remains a reliable method of disinfecting water. Food that is thoroughly cooked and served hot is almost always safe to eat. Dry foods, such as pastry items, breads, and cookies, are generally safe to eat. Unpasteurized milk or other dairy products (cheese) should always be avoided. Breastfeeding should be encouraged for young children, especially infants <6 mo of age, to reduce exposure to contaminated water/formula. All children should be reminded to wash their hands before eating and after playing around soil or animals. Chemoprophylactic agents for traveler's diarrhea are not recommended for children.

Management of Traveler's Diarrhea

Dehydration is the greatest threat presented by a diarrheal illness in a small child. Parents should be made aware of the symptoms and signs of dehydration and should be given instructions on how to administer rehydration solutions. Prepackaged WHO oral rehydration solution packets, which are available at stores or pharmacies in almost all low- and middle-income countries, should be part of a child's travel kit. Oral rehydration solution should be mixed as directed with bottled or boiled water and given slowly, as tolerated, to the child while symptoms persist.

Antimotility agents such as diphenoxylate (Lomotil) and loperamide (Imodium) should be avoided in infants and young children, and the American Academy of Pediatrics does not recommend their routine use in acute gastroenteritis. Use of antimotility agents may be beneficial in older children and adolescents with afebrile, nonbloody traveler's diarrhea. In general, antimotility agents should not distract parents from giving frequent oral rehydration solution, as ongoing intestinal fluid losses likely continue despite a decrease in stooling. Bismuth subsalicylate for acute gastroenteritis should be avoided because of concern for toxicity and Reye syndrome.

Presumptive Antibiotic Treatment

Oral rehydration is the mainstay of treatment for pediatric traveler’s diarrhea. However, antibiotics should be prescribed for the pediatric traveler, with parental instructions to start presumptive treatment early in the diarrheal illness. Systemic antibiotics can shorten the duration and severity of diarrheal illness, especially if presumptive antibiotics are initiated immediately after onset of traveler's diarrhea. For children, the drug of choice is azithromycin (10 mg/kg once daily for up to 3 days, with maximum daily dose of 500 mg). Ciprofloxacin (10 mg/kg per dose twice a day for up to 3 days, maximum dose of 500 mg twice a day) is an alternative for children >1 yr of age, but should not be prescribed for traveler's traveling to the Indian subcontinent or South-east Asia, where fluoroquinolone resistance is common. Shiga-toxin producing E. coli such as E. coli O157:H7 is an extremely uncommon cause of pediatric traveler's diarrhea in nonindustrialized countries, and the benefit of presumptive antibiotic therapy in traveling children, even with bloody diarrhea, typically outweighs the low risk of developing hemolytic-uremic syndrome.

Azithromycin is highly effective against most bacterial pathogens that cause traveler's diarrhea, and is the preferred antibiotic among many travel experts. Azithromycin can be prescribed in powder form that can be reconstituted with safe water into a liquid suspension when needed. In addition, azithromycin 250 mg tablets can be cut to the nearest ¼ tablet size to achieve a dosage of approximately 10 mg/kg, and then crushed and mixed with food or water for younger children. Amoxicillin, trimethoprim-sulfamethoxazole (cotrimoxazole), and erythromycin should not be prescribed for self-treatment of traveler's diarrhea, because of widespread resistance among diarrheal pathogens. Traveler's diarrhea that results in bloody stools, persistently high fevers, systemic chills and rigors, severe or localizing abdominal pain, or continued fluid losses should prompt additional medical evaluation.

INSECT-BORNE INFECTIONS

Insect-borne infections for which traveling children are most at risk include malaria, dengue, chikungunya, yellow fever, and Japanese encephalitis, depending on the area of travel. Malaria is transmitted by night-biting Anopheles mosquitoes, whereas dengue occurs from mosquito species (Culex, Aedes) that are predominantly active during the day. Families should be encouraged to protect children against daytime and nighttime biting mosquitoes, as many regions of the world in which malaria is found also have diseases transmitted by daytime biting mosquitoes (dengue, chikungunya).

Exposure to insect bites can be reduced by wearing appropriate attire and using insect repellents containing N,N-diethyl-m-toluamide (DEET) or picaridin. The American Academy of Pediatrics recommends avoiding DEET-containing repellants in children <2 mo of age. Rare instances of neurologic events have been reported in very young children with exposure to inappropriate, frequent applications of DEET-containing repellants (>10 times a day) or who licked off DEET. Concentrations of 25-30% DEET need be applied every 4-6 hr as needed, whereas 5-7% DEET provides only 1-2 hr of protection time. DEET concentrations >40-50% do not confer a substantially longer protection time for children and generally should be avoided.

Picaridin is a newer insect repellent in the United States but has been used widely in Europe and Australia for yr. Picaridin is fragrance-free, effective, and generally well tolerated on exposed skin and faces. It has similar efficacy to DEET but with less inhalational or dermal irritation.
Picolinate at concentrations of 20% or higher provides adequate protection against Anopheles mosquitoes that have potential to transmit malaria. When applying sunscreen and insect repellent, sunscreen should be applied first followed by DEET or picardin.

Spraying or treating clothing with permethrin, a synthetic pyrethroid, is a safe and effective method of further reducing insect bites in children. Permethrin can be applied directly to clothing, bed nets, shoes, and hats, and should be allowed to fully dry before use. As an insecticide, permethrin should never be applied to skin. Permethrin-treated garments retain both repellency and insecticidal activity, even with repeated laundering. Clothing will eventually need to be retreated to maintain repellency, according to the product label. Bed nets, particularly permethrin-impregnated bed nets, also decrease the risk of insect bites, and their use is highly recommended in malarial areas.

**Malaria Chemoprophylaxis**

Malaria, a mosquito-borne infection, is the leading parasitic cause of death in children worldwide (see Chapter 288). Of the 4 Plasmodium species that infect humans, Plasmodium falciparum causes the greatest morbidity and mortality. Each yr, more than 8 million U.S. citizens visit parts of the world where malaria is endemic (sub-Saharan Africa, Central and South America, India, Southeast Asia, Oceania). Children accounted for 15-20% of imported malaria cases in a WHO study in Europe. Given the major resurgence of malaria and increased travel among families with young children, physicians in industrialized countries are increasingly required to give advice on prevention, diagnosis, and treatment of malaria. Risk factors for severe malaria and death include inadequate adherence to chemoprophylaxis, delay in seeking medical care, delay in diagnosis, and nonimmune status, but the case fatality rate of imported malaria remains <1% in children from nonendemic countries. The CDC maintains updated information at http://www.cdc.gov/malaria/travelers/index.html, as well as a malaria hotline for physicians (770-488-7788). It is important to check this updated information, because recommendations for prophylaxis and treatment are often modified owing to changes in the risk for developing malaria in different areas of the world, changing Plasmodium resistance patterns, and the availability of new antimalarial medications.

Avoidance of mosquitoes and barrier protection from mosquitoes are an important part of malaria prevention for travelers to endemic areas. The Anopheles mosquito feeds from dusk to dawn. Travelers should remain in well-screened areas, wear clothing that covers most of the body, sleep under a net bed (ideally one impregnated with permethrin), and use insect repellents with DEET during these hours. Parents should be discouraged from taking a young child on a trip that will entail evening or nighttime exposure in areas endemic for malaria.

Chemoprophylaxis is the cornerstone of malaria prevention for nonimmune children and adults who travel to malaria-endemic areas but it is not a replacement for other protective measures. Travelers often do not take malaria chemoprophylaxis as prescribed or at all. They are more likely to use prophylactic antimalarial drugs if their physicians provide appropriate recommendations and education before departure. However, in 1 survey, only 14% of persons who sought medical advice obtained correct information about malaria prevention and prophylaxis. Families with children visiting friends and relatives are particularly less likely to take malaria prophylaxis or seek pretravel medical advice.

Resistance of \( P. falciparum \) to the traditional chemoprophylactic agent, chloroquine, is widespread, and in most areas of the world other agents must be used (Table 175-2). Factors that must be considered in choosing appropriate chemoprophylaxis medications and dosing schedules include age of the child, travel itinerary (including whether the child will be traveling to areas of risk within a particular country and whether chloroquine-resistant \( P. falciparum \) is present in the country), vaccinations being given, allergies or other known adverse reactions to antimalarial agents, and the availability of medical care during travel.

Children traveling to areas with chloroquine-resistant \( P. falciparum \) can be given mefloquine, atovaquone-proguanil, or doxycycline (if >8 yr of age) as malaria prophylaxis. For trips shorter than 4 wk, atovaquone-proguanil is the preferred medication, because it is given for only a short period before and after travel. Atovaquone-proguanil or doxycycline is also indicated for travel of any duration to western Cambodia and the Thailand–Cambodia and Thailand–Myanmar borders where of mefloquine resistance in these areas. For periods of travel longer than 4 wk to all other areas with chloroquine-resistant \( P. falciparum \), mefloquine is the preferred medication because it can be taken weekly.

Mefloquine is FDA-approved only for children weighing more than 15 kg, but the CDC recommends mefloquine prophylaxis for all children regardless of weight because the risk for acquiring severe malaria outweighs the risk for potential mefloquine toxicity. Adults taking mefloquine prophylaxis have a 10-25% incidence of sleep disturbance and dysphoria and, less frequently, more serious neuropsychiatric symptoms. These side effects appear to be less common in children. Other potential side effects of mefloquine therapy include nausea and vomiting. The lack of a liquid or suspension formulation can make chloroquine and mefloquine administration difficult. For children who cannot take tablets, parents should take a chloroquine or mefloquine prescription to a compounding pharmacy, which can pulverize the tablets and place exact dosages into gel capsules. Parents can then open the gel capsules and sprinkle the powder into food. “Disguising” these medications, which have a bitter taste, is important; chocolate syrup has been used successfully as a vehicle for the medication. Persons with depression, neuropsychiatric disorders, seizure disorders, and cardiac conduction defects should not take mefloquine.

Atovaquone-proguanil fixed combination (Malarone) is an effective and safe chemoprophylaxis for travelers to chloroquine-resistant malaria-endemic areas, but it is fairly expensive. Adverse drug effects are infrequent and mild (abdominal pain, vomiting, and headache) and infrequently result in discontinuation of the medication. Atovaquone-proguanil prophylaxis must be taken every day with food, so it is better suited for prophylaxis during short periods of exposure. Recent data allow dosing down to 5 kg of body weight, although the use of atovaquone-proguanil at a weight between 5 and 10 kg is considered off-label.

Daily doxycycline is an alternative chemoprophylaxis regimen for chloroquine-resistant \( P. falciparum \) malaria that is considerably less expensive than atovaquone-proguanil. Doxycycline has been used extensively and is highly effective, but it cannot be used in children <8 yr of age owing to the risk of permanent tooth staining, and adverse effects (nausea, vomiting, photosensitivity, vaginal candidiasis) are not uncommon. Persons given doxycycline prophylaxis should be warned to decrease exposure to direct sunlight to minimize the possibility of photosensitivity. Primaquine has also been used successfully as chemoprophylaxis, especially in areas of high prevalence of Plasmodium vivax and Plasmodium ovale, but there are limited data about its use in nonimmune children. Primaquine prophylaxis for children should only be given in consultation with the CDC or a travel medicine specialist. Chloroquine, chloroquine-proguanil, and azithromycin do not provide adequate protection for children traveling to a chloroquine-resistant malaria-endemic area.

In areas of the world where \( P. falciparum \) remains fully chloroquine-sensitive (Haiti, the Dominican Republic, Central America north of the Panama Canal, and some countries in the Middle East), weekly doxycycline is the drug of choice for malaria chemoprophylaxis. Updated information on chloroquine susceptibility and recommended malaria prophylaxis is available at http://wwwnc.cdc.gov/travel/yellowbook/2014/chapter-3-infectious-diseases-related-to-travel/malaria.

On leaving an area endemic for \( P. vivax \) or \( P. ovale \) after a prolonged visit (usually >3 mo), travelers should consider terminal prophylaxis with primaquine (0.5 mg/kg base) daily, up to a maximum of 30 mg base or 52.6 mg salt, for 14 days, to eliminate extraerythrocytic forms of \( P. vivax \) and \( P. ovale \) and prevent relapses. Screening for

*Chloroquine and mefloquine should be started 1-2 wk prior to departure and continued for 4 wk after last exposure.
†Mefloquine resistance exists in western Cambodia and along the Thailand-Cambodia and Thailand-Myanmar borders. Travelers to these areas should take doxycycline or atovaquone-proguanil. See text for precautions about mefloquine use.
‡Doxycycline should be started 1-2 days prior to departure and continued for 4 wk after last exposure. Do not use in children <8 yr of age or in pregnant women.
§Atovaquone-proguanil (Malarone) should be started 1-2 days prior to departure and continued for 7 days after last exposure. Should be taken with food or a milky drink. Not recommended in pregnant women, children who weigh <5 kg, and women breastfeeding infants who weigh <5 kg. Contraindicated in individuals with severe renal impairment (creatinine clearance <30 mL/min).

**glucose-6-phosphate dehydrogenase deficiency is mandatory before primaquine treatment, because primaquine is contraindicated in glucose-6-phosphate dehydrogenase–deficient persons because it can cause severe hemolysis in these persons.**

Small amounts of antimalarial drugs are secreted into breast milk. The amounts of transferred drug are not considered to be either harmful or sufficient to provide adequate prophylaxis against malaria. Prolonged infant exposure to doxycycline via breast milk is not advisable.

Self-treatment of presumptive malaria during travel remains controversial. It should never be substituted for seeking appropriate medical care, but it can be considered in special circumstances such as travel to remote areas, intolerance of prophylaxis, or refusal of chemoprophylaxis by the traveler. Self-treatment medication should be different than the prescribed chemoprophylaxis. The CDC or a travel medicine specialist should be consulted if self-treatment medication is being considered for a traveler.

**THE RETURNING TRAVELER**

Posttravel evaluations are part of travel medicine and continuing care. Physicians unfamiliar with diseases that occur in low- and middle-income countries often misdiagnose the cause of illness in a child returning from travel abroad. Among returning patients identified from GeoSentinal sites who were ill, the common disorders included, in descending order of frequency, malaria, giardiasis, dengue fever, campylobacteriosis, cutaneous larva migrans, enteric fever, spotted

</table>

Thick and thin blood smears need to be performed for diagnosis if malaria is clinically suspected. If results are negative initially, 2 or more additional smears should be done 12-24 hr after the initial smear. Rapid malaria antigen tests (Binax Now) are FDA-approved and sensitive for diagnosing falciparum malaria. Treatment should be initiated immediately once the diagnosis is confirmed or empirically if presentation is severe with suspected malaria. Treatment should be determined in consultation with a pediatric infectious disease specialist and the CDC, which has updated information on the drugs of choice, which are similar to those for adults (see Chapter 288 for more details on malaria infection). Great caution should be used with young children, nonimmune patients, and pregnant patients with falciparum malaria, and hospitalization of these patients should be strongly considered until reliable improvement is observed.

Enteric (typhoid) fever should be considered in children with persistent or recurrent fevers following return from the Indian subcontinent. Multiple blood cultures and a stool culture may both be necessary to diagnosis enteric fever. Dengue is another cause of fever and systemic illness in ill travelers, particularly when returning from Southeast Asia, the Caribbean, Central and South America, or the Indian subcontinent. Many bacterial and protozoal causes of acute traveler’s diarrhea may also result in fever and systemic symptoms in children. Additional travel-associated febrile, diarrheal, and dermatologic illnesses exist, of which the most common etiologies can be found in Table 175-3.

*Bibliography is available at Expert Consult.*

fear (rickettsiosis), chikungunya fever, hepatitis A, and influenza. Returning pediatric travelers who are severely ill or with continued fevers should be seen in consultation with a pediatric travel medicine or infectious diseases physician.

There is very little literature that specifically addresses the causes of illness in children returning from travel. Among all persons returning from travel (children and adults), 3 major patterns of illness have been noted (Table 175-3). The etiology of each of these disease presentations in part depends on the country or geographic region visited.

Fever is a particularly worrisome symptom. Children with a febrile/systemic illness following recent travel to a malarial destination should be promptly evaluated for malaria, especially if having traveled to sub-Saharan Africa and Papua New Guinea. *P. falciparum* malaria will generally present within 1-2 mo after return from travel to a malarial-endemic area, but can occur within the 1st year after return. In contrast, symptoms of *P. vivax*/ *P. ovale* malaria are typically later in onset following travel (i.e., several months), are milder in disease severity, and may occur in a relapsing pattern if undiagnosed or improperly untreated. Other symptoms of malaria can be nonspecific and include chills, malaise, headache, myalgias, vomiting, diarrhea, cough, and possible seizures. Children are more likely than adults to have higher fevers and also gastrointestinal symptoms, hepatomegaly, splenomegaly, and severe anemia. Thrombocytopenia (without increased bleeding) and fever in a child returning from an endemic area are highly suggestive of malaria.

Chapter 176

Fever

Linda S. Nield and Deepak Kamat

DEFINITION

Fever is defined as a rectal temperature ≥38°C (100.4°F), and a value >40°C (104°F) is called hyperpyrexia. Body temperature fluctuates in a defined normal range (36.6-37.9°C [97.9-100.2°F] rectally), so that the highest point is reached in early evening and the lowest point is reached in the morning. Any abnormal rise in body temperature should be considered a symptom of an underlying condition.

PATHOGENESIS

Body temperature is regulated by thermosensitive neurons located in the preoptic or anterior hypothalamus that respond to changes in blood temperature as well as by cold and warm receptors located in skin and muscles. Thermoregulatory responses include redirecting blood to or from cutaneous vascular beds, increased or decreased sweating, regulation of extracellular fluid volume via arginine vasopressin, and behavioral responses, such as seeking a warmer or cooler environmental temperature.

Three different mechanisms can produce fever: pyrogens, heat production exceeding loss, and defective heat loss.

The first mechanism involves endogenous and exogenous pyrogens that raise the hypothalamic temperature set point. Endogenous pyrogens include the cytokines interleukins 1 and 6, tumor necrosis factor α, and interferons β and γ. Stimulated leukocytes and other cells produce lipids that also serve as endogenous pyrogens. The best-studied lipid mediator is prostaglandin E2, which attaches to the prostaglandin receptors in the hypothalamus to produce the new temperature set point. Along with infectious diseases and drugs, malignancy and inflammatory diseases can cause fever through the production of endogenous pyrogens. Some substances produced within the
body are not pyrogens but are capable of stimulating endogenous pyrogens. Such substances include antigen–antibody complexes in the presence of complement, complement components, lymphocyte products, bile acids, and androgenic steroid metabolites.

Exogenous pyrogens or substances that come from outside the body include mainly infectious pathogens and drugs. Microbes, microbial toxins, or other products of microbes are the most common exogenous pyrogens and stimulate macrophages and other cells to produce endogenous pyrogens. Endotoxin is one of the few substances that can directly affect thermoregulation in the hypothalamus as well as stimulate endogenous pyrogen release.

Many drugs cause fever, and the mechanism for increasing body temperature varies with the class of drug. Drugs that are known to cause fever include vancomycin, amphotericin B, and allopurinol.

Heat production exceeding heat loss is the second mechanism that leads to fever, with examples including salicylate poisoning and malignant hyperthermia. Defective heat loss is the third mechanism of fever genesis; for example, in children with ectodermal dysplasia or victims of severe heat exposure.

**ETIOLOGY**

The causes of fever can be organized into 4 main categories: infectious, inflammatory, neoplastic, and miscellaneous. Self-limited viral infections (common cold, gastroenteritis) and uncomplicated bacterial infections (otitis media, pharyngitis, sinusitis) are the most common causes of acute fever. The body temperature rarely rises above potentially lethal levels (42°C [107.6°F]) in the neurologically intact child unless extreme hyperthermic environmental conditions are present or other extenuating circumstances exist, such as underlying malignant hyperthermia or thyrotoxicosis.

The pattern of the fever can provide clues to the underlying etiology. Viral infections typically are associated with a slow decline of fever over a wk, whereas bacterial infections are often associated with a prompt resolution of fever after effective antimicrobial treatment is employed. Although administration of antimicrobial agents can result in a very rapid elimination of bacteria, if tissue injury has been extensive, the inflammatory response and fever can continue for days after all microbes have been eradicated.

Intermittent fever is an exaggerated circadian rhythm that includes a period of normal temperatures on most days; extremely wide fluctuations may be termed septic or hectic fever. Sustained fever is persistent and does not vary by more than 0.5°C (0.9°F)/day. Remittent fever is persistent and varies by more than 0.5°C (0.9°F)/day. Relapsing fever is characterized by febrile periods that are separated by intervals of normal temperature; tertian fever occurs on the 1st and 3rd days (malaria caused by *Plasmodium vivax*), and quartan fever occurs on the 1st and 4th days (malaria caused by *Plasmodium malariae*). Diseases characterized by relapsing fevers (Table 176-1) should be distinguished from infectious diseases that have a tendency to relapse. Biphase fever indicates a single illness with 2 distinct periods (camelback fever pattern); poliomyelitis is the classic example. A biphase course is also characteristic of other enteroviral infections, leptospirosis, dengue fever, yellow fever, Rocky Mountain spotted fever, or acute bacterial endocarditis.

**CLINICAL FEATURES**

The clinical features of fever can range from no symptoms at all to extreme malaise. Children might complain of feeling hot or cold, display facial flushing, and experience shivering. Fatigue and irritability may be evident. Parents often report that the child looks ill or pale and has a decreased appetite. The underlying etiology also produces accompanying symptoms. Although the underlying etiologies can manifest in varied ways clinically, there are some predictable features. For instance, fever with petechiae in an ill-appearing patient indicates the high possibility of life-threatening conditions such as meningococcemia, Rocky Mountain spotted fever, or acute bacterial endocarditis.
Evaluation of Acute Fever

Changes in heart rate, most commonly tachycardia, accompany fever. Normally heart rate rises by 10 beats/min per 1°C (1.8°F) rise in temperature for children >2 mo of age. Relative tachycardia, when the pulse rate is elevated disproportionately to the temperature, is usually caused by noninfectious diseases or infectious diseases in which a toxin is responsible for the clinical manifestations. Relative bradycardia (temperature–pulse dissociation), when the pulse rate remains low in the presence of fever, can accompany typhoid fever, brucellosis, leptospirosis, or drug fever. Bradycardia in the presence of fever also may be a result of a conduction defect resulting from cardiac involvement with acute rheumatic fever, Lyme disease, viral myocarditis, or infective endocarditis.

**EVALUATION**

Most acute febrile episodes in a normal host can be diagnosed by a careful history and physical examination and require few, if any, laboratory tests. Because infection is the most likely etiology of the acute fever, the evaluation should initially be geared to discovering an underlying infectious cause (Table 176-2). The details of the history should include the onset and pattern of fever and any accompanying signs and symptoms. The patient often displays signs or symptoms that provide clues to the cause of the fever. Exposures to other ill persons at home, daycare, and school should be noted, along with any recent travel or medications. The past medical history should include information about underlying immune deficiencies or other major illnesses and receipt of childhood vaccines.

Physical examination should begin with a complete evaluation of vital signs, which should include pulse oximetry because hypoxia may indicate lower respiratory infection. In the acutely febrile child, the physical examination should focus on any localized complaints, but a complete head-to-toe screen is recommended, because clues to the underlying diagnosis may be found. For example, palsy and sole lesions may be discovered during a thorough skin examination and provide a clue for infection with coxsackievirus.

If a fever has an obvious cause, then laboratory evaluation may not be required, and management is tailored to the underlying cause with as-needed reevaluation. If the cause of the fever is not apparent, then further diagnostic evaluation should be considered on a case-by-case basis. The history of presentation and abnormal physical examination findings guide the evaluation. The child with respiratory symptoms and hypoxia may require a chest radiograph or rapid antigen testing for respiratory syncytial virus or influenza. The child with pharyngitis can benefit from rapid antigen detection testing for group A Streptococcus and a throat culture. Dysuria, back pain, or a history of vesicoureteral reflux should prompt a urinalysis and urine culture, and bloody diarrhea should prompt a stool culture. A complete blood count and blood culture should be considered in the ill-appearing child, along with cerebrospinal fluid studies if the child has neck stiffness or if the possibility of meningitis is considered. Well-defined high-risk groups require a more-extensive evaluation on the basis of age, associated disease, or immunodeficiency status, and might warrant prompt antimicrobial therapy before a pathogen is identified. The evaluations of infants <3 mo of age and children with recurrent fevers are discussed in Chapter 177.

**MANAGEMENT**

Although fear of fever is a common parental worry, evidence is lacking to support the belief that high fever can result in brain damage or other bodily harm, except in rare instances of febrile status epilepticus and heatstroke. Treating fever in self-limiting illnesses for the sole reason of bringing the body temperature back to normal is not necessary in the otherwise healthy child. Most evidence suggests that fever is an adaptive response and should be treated only in selected circumstances. In humans, increased temperatures are associated with decreased microbial replication and an increased inflammatory response. Although fever can have beneficial effects, it also increases oxygen consumption, carbon dioxide production, and cardiac output, and can exacerbate cardiac insufficiency in patients with heart disease or chronic anemia (e.g., sickle cell disease), pulmonary insufficiency in patients with chronic lung disease, and metabolic instability in patients with diabetes mellitus or inborn errors of metabolism. Children between the ages of 6 mo and 5 yr are at increased risk for simple febrile seizures. The focus of the evaluation and treatment of febrile seizures is aimed at determining the underlying cause of the fever. Children with idiopathic epilepsy also often have an increased frequency of seizures associated with a fever. High fever during pregnancy may be teratogenic.

Fever with temperatures <39°C (102.2°F) in healthy children generally does not require treatment. However, as temperatures become higher, patients tend to become more uncomfortable, and treatment of fever is then reasonable. If a child is included in 1 of the high-risk groups or if the child’s caregiver is concerned that the fever is adversely affecting the child’s behavior and causing discomfort, treatment may be given to hasten the resolution of the fever. Other than providing symptomatic relief, antipyretic therapy does not change the course of infectious diseases. Encouraging good hydration is the first step to replace fluids that are lost related to the increased metabolic demands of fever. Antipyretic therapy is beneficial in high-risk patients who have chronic cardiopulmonary diseases, metabolic disorders, or neurologic diseases and in those who are at risk for febrile seizures.

Hyperpyrexia (>41°C [105.8°F]) indicates high probability of hypothalamic disorders or central nervous system hemorrhage and should be treated with antipyretics. Some studies show that hyperpyrexia may be associated with a significantly increased risk of serious bacterial infection, but other studies have not substantiated this relationship. Acetaminophen at a dose of 10-15 mg/kg/dose every 4 hr and ibuprofen in children >6 mo at a dose of 5-10 mg/kg/dose every 8 hr are the most commonly employed antipyretics. Antipyretics reduce fever by reducing production of prostaglandins. If used appropriately, antipyretics are safe; potential adverse effects include liver damage (acetaminophen) and gastrointestinal or kidney disturbances (ibuprofen). To reduce fever most safely, the caregiver should choose 1 type of medication and clearly record the dose and time of administration, so overdosage does not occur, especially if multiple caregivers are involved in the management. Physical measures such as tepid baths and cooling blankets are not considered effective to reduce fever. Evidence is also scarce for the use of complementary and alternative medicine interventions.

Fever caused by specific underlying etiologies resolves when the condition is properly treated. Examples include administration of intravenous immunoglobulin to treat Kawasaki disease or the administration of antibiotics to treat bacterial infections.

Chapter 176  ❖ Fever  1279
Bibliography

**Fever without a focus** refers to a rectal temperature of 38°C (100.4°F) or higher as the sole presenting feature. The terms “fever without localizing signs” and “fever of unknown origin” (FUO) are subcategories of fever without a focus.

**FEVER WITHOUT LOCALIZING SIGNS**
Fever of acute onset, with duration of <1 wk and without localizing signs, is a common diagnostic dilemma in children <36 mo of age. The etiology and evaluation of fever without localizing signs depends on the age of the child. Traditionally, 3 age groups are considered: neonates or infants to 1 mo of age, infants >1 mo to 3 mo of age, and children >3 mo to 3 yr of age. In 1993, practice guidelines were published to aid the clinician in evaluating the otherwise healthy 0-36 mo old child with fever without a source. However, with the advent and extensive use of the conjugate Haemophilus influenzae type b (Hib) and Streptococcus pneumoniae vaccines, the rates of infections with these 2 pathogens have decreased substantially. As a consequence, modifications to the 1993 guidelines have been advocated as described in the section “3-36 Months of Age.” Children in high-risk groups (Table 177-1) require a more aggressive diagnostic approach and consideration of a broader differential diagnosis.

**Neonates**
Neonates who experience fever without focus are a challenge to evaluate because they display limited signs of infection, making it difficult to clinically distinguish between a serious bacterial or viral (herpes simplex virus [HSV]) infection and self-limited viral illness. Immature immune responses in the 1st few mo of life also increase the significance of fever in the young infant. In general, neonates who have a fever and do not appear ill have a 7% risk of having a serious bacterial infection. Serious bacterial infections include bacteremia, meningitis, pneumonia, osteomyelitis, septic arthritis, enteritis, and urinary tract infections. Although neonates with serious infection can acquire community pathogens, they are mainly at risk for late-onset neonatal bacterial diseases (group B streptococci, *E. coli*, and *Listeria monocytogenes*) and perinatally acquired herpes simplex virus (HSV) infection.

Practice guidelines recommend that if a neonate has had a fever recorded at home by a reliable parent, the patient should be treated as a febrile neonate. If excessive clothing and blankets encasing the infant are suspected of falsely elevating the body temperature, then the excessive coverings should be removed and the temperature retaken in 15-30 min. If body temperature is normal after the covers are removed, then the infant is considered afebrile.

Owing to the unreliability of physical findings and the presence of an immature immune system, all febrile neonates should be hospitalized; blood, urine, and cerebrospinal fluid (CSF) should be cultured, and the child should receive empirical intravenous antibiotics. CSF studies should include cell counts, glucose and protein levels, Gram stain, and culture; HSV and enterovirus polymerase chain reaction should be considered. Stool culture and chest radiograph may also be part of the evaluation. Combination antibiotics, such as ampicillin and cefotaxime or ampicillin and gentamicin, are recommended. Acyclovir should be included if HSV infection is suspected because of seizures, hypotension, transaminase elevation, CSF pleocytosis, or known maternal history of genital HSV, especially at the time of delivery.

**1 to 3 Months of Age**
The large majority of children with fever without localizing signs in the 1-3 mo age group likely have a viral syndrome. In contrast to bacterial infections, most viral diseases have a distinct seasonal pattern: respira-

---

tory syncytial virus and influenza A virus infections are more common during the winter, whereas enterovirus and parechovirus infections usually occur in the summer and fall. Although a viral infection is the most likely etiology, fever in this age group should always suggest the possibility of serious bacterial disease. Organisms to consider include *E. coli*, group B *Streptococcus*, *L. monocytogenes*, *S. pneumoniae*, *N. meningitidis*, *S. pneumoniae*, *H. influenzae* type b, and *S. aureus*. Pyelonephritis is the most common serious bacterial infection in this age group and is also more common in uncircumcised infant boys and infants with urinary tract anomalies. *E. coli* is the most common pathogen identified in bacteremic infants, the majority having pyelonephritis. Group B *Streptococcus* followed by *S. aureus* are the next most frequently identified pathogens causing bacteremia; pneumococcus tends to be seen in older infants. Most significant blood cultures turn positive within 24 hr (91%), with 99% positive by 48 hr. Other potential bacterial diseases in this age group include otitis media, pneumonia, omphalitis, mastitis, and other skin and soft tissue infections. Ill-appearing (toxic) febrile infants 3 mo of age younger require prompt hospitalization and immediate parenteral antimicrobial therapy after cultures of blood, urine, and CSF are obtained. Ampicillin (to cover *L. monocytogenes* and *Enterococcus*) plus either ceftriaxone
or cefotaxime is an effective initial antimicrobial regimen for ill-
appearing infants without focal findings. This regimen is effective
against the usual bacterial pathogens causing sepsis, urinary tract
infection, and enteritis in young infants. However, if meningitis is
suspected because of CSF abnormalities, vancomycin should be
included to treat possible penicillin-resistant S. pneumoniae until the
results of culture and susceptibility tests are known.

Many academic institutions have investigated the optimal manage-
ment of low-risk patients in this age group with fever without a focus
(Table 177-2). The use of viral diagnostic studies (enteroviruses, par-
chovirus, respiratory viruses, rotavirus, and herpesvirus) in combina-
tion with the Rochester Criteria or similar criteria can enhance the
ability to determine which infants are at high risk for serious bacterial
infections (Table 177-2). Febrile infants in whom a virus has been
detected are at low or no risk of a serious bacterial infection. Well-
appearing infants 1-3 mo of age can be managed safely using low-risk
laboratory and clinical criteria as indicated in Table 177-2 if reliable
parents are involved and close follow-up is assured.

Infants 1-3 mo of age with fever who appear generally well; who
have been previously healthy; who have no evidence of skin, soft tissue,
bone, joint, or ear infection; and who have a peripheral white blood cell
(WBC) count of 5,000-15,000 cells/µL, an absolute band count of
<1,500 cells/µL, and normal urinalysis and negative culture (blood and
urine) results are unlikely to have a serious bacterial infection. The
negative predictive value with 95% confidence of these criteria for any
serious bacterial infection is >98% and for bacteremia is >99%. Among
serious bacterial infections, pyelonephritis is the most common and
may be seen in well-appearing infants who have fever without a focus
or in those who appear ill. Urinalysis may be negative in infants <2 mo
of age with pyelonephritis. Bacteremia is present in <30% of infants
with pyelonephritis. Procalcitonin, erythrocyte sedimentation rate
(ESR), and C-reactive protein are biologic markers that may be con-
sidered in the evaluation of a child with fever. Host-based microarray
gene expression profiles determined on the patient’s leukocytes may be
able to detect RNA transcriptional patterns (biosignatures) that distin-
guish viral from bacterial infection (Fig. 177-1).

The decision to obtain CSF studies in the well-appearing 1-3 mo old
infant depends on the decision to administer empirical antibiotics. If
close observation without antibiotics is planned, a lumbar puncture
may be deferred. If the child deteriorates clinically, a full sepsis eval-
uation should be performed, and intravenous antibiotics should be
administered. If empirical antibiotics are initiated, CSF studies should
be obtained, preferably before administering antibiotics.

### 3 to 36 Months of Age

Approximately 30% of febrile children in the 3-36 mo age group have
no localizing signs of infection. Viral infections are the cause of the
vast majority of fevers in this population, but serious bacterial infec-
tions do occur and are caused by the same pathogens listed for patients
1-3 mo of age, except for the perinatally acquired infections. S. pneu-
moniae, N. meningitidis, and Salmonella account for most cases of
occult bacteremia. H. influenzae type b was an important cause of
occult bacteremia in young children before universal immunization
with conjugate Hib vaccines and remains common in underdeveloped
countries that have not implemented these vaccines in their immu-

### Table 177-2 Low-Risk Criteria in a Child 1-3 Months Old with Fever

**BOSTON CRITERIA**

Infants are at low risk if they appear well, have a normal physical
examination, and have a caretaker reachable by telephone if laboratory tests are as follows:

- CBC: <20,000 WBC/µL
- Urine: negative leukocyte esterase
- CSF: leukocyte count less than 10 x 10⁶/L

**PHILADELPHIA PROTOCOL**

Infants are at low risk if they appear well and have a normal physical examination and if laboratory tests are as follows:

- CBC: <15,000 WBC/µL; band total neutrophil ratio <0.2
- Urine: <10 WBC/HPF; no bacteria on Gram stain
- CSF: <8 WBC/µL; no bacteria on Gram stain
- Chest radiograph: no infiltrate
- Stool: no RBC; few to no WBC

**PITTSBURGH GUIDELINES**

Infants are at low risk if they appear well and have a normal physical examination and if laboratory tests are as follows:

- CBC: 5,000-15,000 WBC/µL; peripheral absolute band count <1,500/µL
- Urine (enhanced urinalysis): 9 WBC/µL and no bacteria on Gram stain
- CSF: 5 WBC/µL and negative Gram stain; if bloody tap, then WBC:RBC ≤1:500
- Chest radiograph: no infiltrate
- Stool: 5 WBC/HPF with diarrhea

**ROCHESTER CRITERIA**

Infants are at low risk if they appear well and have a normal physical examination and if laboratory findings are as follows:

- CBC: 5,000-15,000 WBC/µL; absolute band count ≤1,500/µL
- Urine: <10 WBC/HPF at 40x
- Stool: ≤5 WBC/HPF if diarrhea

CBC, complete blood count; CSF, cerebrospinal fluid; HPF, high-powered field; RBC, red blood cell; WBC, white blood cell.

**Figure 177-1 Gene expression patterns may discriminate viral vs bacterial infections.**

A. Set of 35 genes that discriminates patients with viral infections (influenza A; green) and bacterial infections (Escherichia coli and Streptococcus pneumoniae; red). The discriminative pattern is shown by the gene expression patterns in the heat map (red indicates overexpressed genes; blue indicates underexpressed genes). B. The diagnostic signature was tested in an independent set of patients that confirmed its accuracy. K-NN indicates nearest neighbor algorithm. (Modified from Ramilo O, Allman W, Chung W, et al: Gene expression patterns in blood leukocytes discriminate patients with acute infections, Blood 109:2066-2077, 2007. Fig 1.)
elevated absolute neutrophil count, band count, erythrocyte sedimentation rate (ESR), or C-reactive protein. The probability of bacteremia and/or pneumonia or pyelonephritis among infants 3-36 mo of age increases as the temperature (especially >38°C [100.4°F]) and WBC count (especially >25,000/µL) increase. However, no combination of laboratory tests or clinical assessment is sensitive enough to predict the presence of occult bacteremia. Socioeconomic status, race, gender, and age (within the range of 3-36 mo) do not appear to affect the risk for occult bacteremia.

The pattern of sequelae of occult bacteremia may be related to host factors and the offending organism. In some children, the occult bacteremic illness can represent the early signs of serious localized infection rather than a transient disease state. Without therapy, occult bacteremia caused by pneumococcus can resolve spontaneously without sequelae, or persist, or can lead to localized infections such as meningitis, pneumonia, cellulitis, pericarditis, or suppurrative arthritis. Among patients with pneumococcal bacteremia (occult or focal), spontaneous resolution occurs in 30-40%, with a higher rate of spontaneous resolution among well-appearing children.

Hib bacteremia is characteristicly associated with a higher risk for localized serious infection than is bacteremia caused by S. pneumoniae. Hospilized children with Hib bacteremia often develop focal infections, such as meningitis, epiglottitis, cellulitis, pericarditis, or osteo-articular infection, and spontaneous resolution of bacteremia is rare. Important bacterial infections among children 3-36 mo of age with localizing signs include otitis media, sinusitis, pneumonia (not always evident without a chest radiograph), enteritis, urinary tract infection, osteomyelitis, and meningitis.

Management of toxic-appearing febrile children 3-36 mo of age who do not have focal signs of infection includes hospitalization and prompt institution of antimicrobial therapy after specimens of blood, urine, and CSF are obtained for culture. Consensus practice guidelines published in 1993 recommended that children 3-36 mo of age who have a temperature of <39°C (102.2°F) and do not appear toxic be observed as outpatients without performing diagnostic tests or administering antimicrobial agents. For nontoxic-appearing infants with a rectal temperature of ≥39°C (102.2°F), options include obtaining a blood culture and administering empirical antibiotic therapy (ceftriaxone, a single dose of 50 mg/kg, not to exceed 1 g); if the WBC count is >15,000/µL, obtaining a blood culture and beginning empirical ceftriaxone; or obtaining a blood culture and observing as outpatients without empirical antibiotic therapy, with return for reevaluation within 24 hr. Guideline for managing febrile children 3-36 mo of age who have received both Hib and S. pneumoniae conjugate vaccines have not been established, but careful observation without empirical administration of antibiotic therapy is generally prudent. Because fully vaccinated young children are at a much lower risk of occult bacteremia and meningitis as the cause of acute fever without localizing signs, some advocate that the only laboratory tests needed in this age group when temperature is >39°C (102.2°F) are a urinalysis and urine culture for circumcised boys <6 mo of age and uncircumcised boys and all girls <24 mo of age. Regardless of the management option (Table 177-3), the family should be instructed to return immediately if the child's condition deteriorates or new symptoms develop.

Empirical antibiotic therapy for well-appearing children <36 mo of age who have not received Hib and S. pneumoniae conjugate vaccines and who have a rectal temperature of >39°C (102.2°F) and a WBC count of >15,000/µL is strongly recommended. If blood cultures are obtained and S. pneumoniae is isolated from the blood, the child should return to the physician as soon as possible after the culture results are known. If the child appears well, is afebrile, and has a normal physical exam, a second blood culture should be obtained and the child should be treated with 7-10 days of oral antimicrobial therapy. If the child appears ill and continues to have fever with no identifiable focus of infection at the time of follow-up, or if H. influenzae or N. meningitidis is present in the initial blood culture, the child

should have a repeat blood culture, be evaluated for meningitis (including lumbar puncture), and receive treatment in the hospital with appropriate intravenous antimicrobial agents. If the child develops a localized infection, therapy should be directed toward the likely pathogens.

**FEVER OF UNKNOWN ORIGIN**

The classification of fever of unknown origin (FUO) is best reserved for children with fever documented by a healthcare provider and for which the cause could not be identified after 3 wk of evaluation as an outpatient or after 1 wk of evaluation in the hospital (Table 177-4).

**Etiology**

The many causes of FUO in children are infections, rheumatologic (connective tissue or autoimmune) diseases, or autoinflammatory diseases (see Chapter 163) (Table 177-5). Neoplastic disorders should also be seriously considered, although most children with malignancies do not have fever alone. The possibility of drug fever should be considered if the patient is receiving any drug. Drug fever is usually sustained and not associated with other symptoms. Discontinuation of the drug is associated with resolution of the fever, generally within 72 hr, although certain drugs, such as iodides, are excreted for a prolonged period with fever that can persist for as long as 1 mo after drug withdrawal.

Most fevers of unknown or unrecognized origin result from atypical presentations of common diseases. In some cases, the presentation as an FUO is characteristic of the disease, such as juvenile idiopathic arthritis, but the definitive diagnosis can be established only after prolonged observation because initially there are no associated or specific findings on physical examination and all laboratory results are negative or normal.

In the United States, the systemic infectious diseases most commonly implicated in children with FUO are salmonellosis, tuberculosis, rickettsial diseases, syphilis, Lyme disease, cat-scratch disease, atypical prolonged presentations of common viral diseases, Epstein-Barr virus infection, cytomegalovirus (CMV) infection, viral hepatitis, coccidioidomycosis, histoplasmosis, malaria, and toxoplasmosis. Less-common infectious causes of FUO include tularemia, brucellosis, leptospirosis, and rat bite fever. AIDS alone is not usually responsible for FUO, although febrile illnesses often occur in patients with AIDS as a result of opportunistic infections (see Table 177-4).

Juvenile idiopathic arthritis (JIA) and systemic lupus erythematosus are the connective tissue diseases associated most commonly with FUO. Inflammatory bowel disease and Kawasaki disease are also commonly reported as causes of FUO. If factitious fever (inoculation of pyogenic material or manipulation of the thermometer by the patient or parent) is suspected, the presence and pattern of fever should be documented in the hospital. Prolonged and continuous observation, which can include electronic or video surveillance, of patients is imperative. FUO lasting longer than 6 mo is uncommon in children and suggests granulomatous, autoinflammatory, or autoimmune disease.

</table>
Repeat interval evaluation, including history, physical examination, laboratory evaluation, and imaging studies, is required.

**Diagnosis**

The evaluation of FUO requires a thorough history and physical examination supplemented by a few screening laboratory tests and additional laboratory and imaging evaluation as indicated by the history or abnormalities on examination or initial screening tests (see Table 177-6).

**History**

A detailed fever history including onset, frequency, duration of fever, response or nonresponse to therapy, recurrence, and associated symptoms should be obtained. Repetitive chills and temperature spikes are common in children with septicemia (regardless of cause), particularly when associated with kidney disease, liver or biliary disease, infective endocarditis, malaria, brucellosis, rat bite fever, or a localized collection of pus.

The age of the patient is helpful in evaluating FUO. Children > 6 yr of age often have a respiratory or genitourinary tract infection, localized infection (abscess, osteomyelitis), JIA, or, rarely, leukemia. Adolescent patients are more likely to have inflammatory bowel disease, autoimmune processes, lymphoma, or tuberculosis, in addition to the causes of FUO found in younger children.

A history of exposure to wild or domestic animals should be solicited. The incidence of zoonotic infections in the United States is increasing, and these infections are often acquired from pets that are not overtly ill. Immunization of dogs against specific disorders such as leptospirosis can prevent canine disease but does not always prevent the animal from carrying and shedding leptospires, which may be transmitted to household contacts. A history of ingestion of rabbit or squirrel meat might provide a clue to the diagnosis of oropharyngeal, transmitted to household contacts. A history of ingestion of rabbit or squirrel meat might provide a clue to the diagnosis of oropharyngeal, glandular, or typhoidal tularemia. A history of tick bite or travel to tick- or parasite-infested areas should be obtained.

Any history of pica should be elicited. Ingestion of dirt is a particularly important clue to infection with Toxocara canis (visceral larva migrans) or Toxoplasma gondii (toxoplasmosis).

A history of unusual dietary habits or travel as early as the birth of the child should be sought. Malaria, histoplasmosis, and coccidioidomycosis can reemerge years after visiting or living in an endemic area. It is important to identify prophylactic immunizations and precautions taken by the patient against ingestion of contaminated water or food during foreign travel. Rocks, dirt, and artifacts from geographically distant regions that have been collected and brought into the home as souvenirs can serve as vectors of disease.

A medication history should be pursued rigorously. This history should elicit information about nonprescription preparations and topical agents, including eyedrops, that may be associated with atropine-induced fever.

The genetic background of a patient also is important. Descendants of the Ulster Scots may have FUO because they are afflicted with nephrogenic diabetes insipidus. Familial dysautonomia (Riley-Day syndrome), a disorder in which hyperthermia is recurrent, is more common among Jews than among other population groups. Ancestry from the Mediterranean region should suggest the possibility of familial Mediterranean fever. Both familial Mediterranean fever and hyperimmunoglobulin D syndrome are inherited as autosomal recessive disorders. Tumor necrosis factor receptor–associated periodic syndrome and Muckle-Wells syndrome are inherited as autosomal dominant traits.

**Physical Examination**

A complete physical examination is essential to search for any clues to the underlying diagnosis (Table 177-6). The child's general appearance, including sweating during fever, should be noted. The continuing absence of sweat in the presence of an elevated or changing body temperature suggests dehydration due to vomiting, diarrhea, or central or nephrogenic diabetes insipidus. It also should suggest anhidrotic ectodermal dysplasia, familial dysautonomia, or exposure to atropine. The general activity of the patient and the presence or absence of rashes should also be noted.

A careful ophthalmic examination is important. Red, weeping eyes may be a sign of connective tissue disease, particularly polyarteritis nodosa. Palpebral conjunctivitis in a febrile patient may be a clue to measles, coxsackievirus infection, tuberculosis, infectious mononucleosis, lymphogranuloma venereum, or cat-scratch disease. In contrast, bulbar conjunctivitis in a child with FUO suggests Kawasaki disease or leptospirosis. Petechial conjunctival hemorrhages suggest infectious mononucleosis, histoplasmosis, and coccidioidomycosis.

*Includes tuberculosis, histoplasmosis, coccidioidomycosis, sarcoïdosis, granulomatosis with polyangiitis, and syphilis.

The ophthalmoscope should also be used to examine nainfold capillary abnormalities that are associated with connective tissue diseases such as juvenile dermatomyositis and systemic scleroderma. Immer- sion oil or lubricating jelly is placed on the skin adjacent to the nail bed, and the capillary pattern is observed with the ophthalmoscope set on +40.

FUO is sometimes caused by hypothalamic dysfunction. A clue to this disorder is failure of pupillary constriction because of absence of the sphincter constrictor muscle of the eye. This muscle develops embryologically when hypothalamic structure and function also are undergoing differentiation.

Fever resulting from familial dysautonomia may be suggested by lack of tears, an absent corneal reflex, or a smooth tongue with absence of fungiform papillae. Tenderness to tapping over the sinuses or the upper teeth suggests sinusitis. Recurrent oral candidiasis may be a clue to various disorders of the immune system especially involving the T lymphocytes. Hyperactive deep tendon reflexes can suggest thryotoxicosis as the cause of FUO.

Fever blisters are common findings in patients with pneumococcal, streptococcal, malarial, and rickettsial infection as well as periodic fever syndromes. These lesions also are common in children with meningococccal meningitis (which usually does not manifest as FUO) but rarely are seen in children with meningococcemia. Fever blisters also are occasionally seen with Salmonella or staphylococcal infections.

Hyperemia of the pharynx, with or without exudate, suggests streptococcal infection, Epstein-Barr virus infection, CMV infection, toxoplasmosis, salmonellosis, tularemia, Kawasaki disease, or leptospirosis.

The muscles and bones should be palpated carefully. Point tenderness over a bone can suggest occult osteomyelitis or bone marrow invasion from neoplastic disease. Tenderness over the trapezius muscle may be a clue to subdiaphragmatic abscess. Generalized muscle tenderness suggests dermatomyositis, trichinosis, polyarteritis, Kawasaki disease, or myoplasmal or avbriortal infection.

Rectal examination can reveal perirectal lymphadenopathy or tenderness, which suggests a deep pelvic abscess, iliac adenitis, or pelvic osteomyelitis. A guaic test should be obtained; occult blood loss can suggest granulomatous colitis or ulcerative colitis as the cause of FUO.

**Laboratory Evaluation**

The laboratory evaluation of the child with FUO and whether the evaluation will occur in the inpatient or outpatient realm are determined on a case-by-case basis. Hospitalization may be required for laboratory or imaging studies that are unavailable or impractical in an ambulatory setting, for more-careful observation, or for temporary relief of patients’ anxiety. The tempo of diagnostic evaluation should be adjusted to the tempo of the illness; haste may be imperative in a critically ill patient, but if the illness is more chronic, the evaluation can proceed in systematic fashion and can be carried out in an outpatient setting. If there are no clues in the patient’s history or on physical examination that suggest a specific infection or area of suspicion, it is unlikely that diagnostic studies will be helpful. In that common scenario, continued surveillance and repeated reevaluations of the child should be employed to detect any new clinical findings.

Although ordering a large number of diagnostic tests in every child with FUO according to a predetermined list is discouraged, certain studies should be considered in the evaluation. A complete blood cell count with a differential WBC count and a urinalysis should be part of the initial laboratory evaluation. An absolute neutrophil count of <5,000/µL is evidence against indolent bacterial infection other than typhoid fever. Conversely, in patients with a polymorphonuclear leukocyte count of >10,000/µL or a nonsegmented polymorphonuclear leukocyte count of >500/µL a severe bacterial infection is highly likely.

Direct examination of the blood smear with Giemsa or Wright stain can reveal organisms of malaria, trypanosomiasis, babesiosis, or relapsing fever.

An ESR of >30 mm/hr indicates inflammation and the need for further evaluation for infectious, autoimmune, autoinflammatory, or malignant diseases, tuberculosis, Kawasaki disease, or autoimmune disease. A low ESR does not eliminate the possibility of infection or JIA. C-reactive protein is another acute-phase reactant that becomes elevated and returns to normal more rapidly than the ESR. Experts recommend checking 1 of the 2 because there is no evidence that measuring both the ESR and C-reactive protein in the same patient with FUO is clinically useful.

Blood cultures should be obtained aerobically. Anaerobic blood cultures have an extremely low yield and should be obtained only if there are specific reasons to suspect anaerobic infection. Multiple or repeated blood cultures may be required to detect bacteremia associated with infective endocarditis, osteomyelitis, or deep-seated abscesses. Polymicrobial bacteremia suggests factitious self-induced infection or gastrointestinal (GI) pathology. The isolation of leptospires, Francisella, or Yersinia requires selective media or specific conditions not routinely used. Therefore, it is important to inform the laboratory what organisms you are suspecting in a particular case. Urine culture should be obtained in all cases.

Tuberculin skin testing should be performed with intradermal placement of 5 units of purified protein derivative that has been kept appropriately refrigerated.

Imaging studies of the chest, sinuses, mastoids, or GI tract may be indicated by specific historical or physical findings. Radiographic evaluation of the GI tract for inflammatory bowel disease may be helpful in evaluating selected children with FUO and no other localizing signs or symptoms.

Examination of the bone marrow can reveal leukemia; metastatic neoplasm; mycobacterial, fungal, or parasitic infections; histiocytosis; hemophagocytosis; or storage diseases. If a bone marrow aspirate is performed, cultures for bacteria, mycobacteria, and fungi should be obtained.

Serologic tests can aid in the diagnosis of Epstein-Barr virus infection, CMV infection, toxoplasmosis, salmonellosis, tularemia, brucellosis, leptospirosis, cat-scratch disease, Lyme disease, rickettsial disease, and, on some occasions, JIA. The clinician should be aware that the reliability and sensitivity and specificity of these tests vary; for instance, serologic tests for Lyme disease outside of reference laboratories have been generally unreliable.

Radionuclide scans may be helpful in detecting abdominal abscesses as well as osteomyelitis, especially if the focus cannot be localized to a specific limb or multifocal disease is suspected. Gallium citrate localizes inflammatory tissues (leukocytes) associated with tumors or abscesses. Technetium-99m phosphate is useful for detecting osteomyelitis before plain roentgenograms demonstrate bone lesions. Granulocytes tagged with indium or iodinated immunoglobulin G may be useful in detecting localized pyogenic processes. 18-F-fluorodeoxyglucose positron emission tomography is a helpful imaging modality in adults with an FUO and can contribute to an ultimate diagnosis in 30-60% of patients. Echocardiograms can demonstrate the presence of a vegeting fever.

Direct examination of the blood smear with Giemsa or Wright stain can reveal organisms of malaria, trypanosomiasis, babesiosis, or relapsing fever.

A low ESR does not eliminate the possibility of infection or JIA. C-reactive protein is another acute-phase reactant that becomes elevated and returns to normal more rapidly than the ESR. Experts recommend checking 1 of the 2 because there is no evidence that measuring both the ESR and C-reactive protein in the same patient with FUO is clinically useful.

Blood cultures should be obtained aerobically. Anaerobic blood cultures have an extremely low yield and should be obtained only if there are specific reasons to suspect anaerobic infection. Multiple or repeated blood cultures may be required to detect bacteremia associated with infective endocarditis, osteomyelitis, or deep-seated abscesses. Polymicrobial bacteremia suggests factitious self-induced infection or gastrointestinal (GI) pathology. The isolation of leptospires, Francisella, or Yersinia requires selective media or specific conditions not routinely used. Therefore, it is important to inform the laboratory what organisms you are suspecting in a particular case. Urine culture should be obtained in all cases.

Tuberculin skin testing should be performed with intradermal placement of 5 units of purified protein derivative that has been kept appropriately refrigerated.

Imaging studies of the chest, sinuses, mastoids, or GI tract may be indicated by specific historical or physical findings. Radiographic evaluation of the GI tract for inflammatory bowel disease may be helpful in evaluating selected children with FUO and no other localizing signs or symptoms.

Examination of the bone marrow can reveal leukemia; metastatic neoplasm; mycobacterial, fungal, or parasitic infections; histiocytosis; hemophagocytosis; or storage diseases. If a bone marrow aspirate is performed, cultures for bacteria, mycobacteria, and fungi should be obtained.

Serologic tests can aid in the diagnosis of Epstein-Barr virus infection, CMV infection, toxoplasmosis, salmonellosis, tularemia, brucellosis, leptospirosis, cat-scratch disease, Lyme disease, rickettsial disease, and, on some occasions, JIA. The clinician should be aware that the reliability and sensitivity and specificity of these tests vary; for instance, serologic tests for Lyme disease outside of reference laboratories have been generally unreliable.

Radionuclide scans may be helpful in detecting abdominal abscesses as well as osteomyelitis, especially if the focus cannot be localized to a specific limb or multifocal disease is suspected. Gallium citrate localizes inflammatory tissues (leukocytes) associated with tumors or abscesses. Technetium-99m phosphate is useful for detecting osteomyelitis before plain roentgenograms demonstrate bone lesions. Granulocytes tagged with indium or iodinated immunoglobulin G may be useful in detecting localized pyogenic processes. 18-F-fluorodeoxyglucose positron emission tomography is a helpful imaging modality in adults with an FUO and can contribute to an ultimate diagnosis in 30-60% of patients. Echocardiograms can demonstrate the presence of a vegetation on the leaflets of heart valves, suggesting infective endocarditis. Ultrasonography can identify intraabdominal abscesses of the liver, subphrenic space, pelvis, or spleen.

Total-body CT or MRI (both with contrast) is usually the imaging study of choice; both permit detection of neoplasms and collections of purulent material without the use of surgical exploration or radioisotopes. CT and MRI are helpful in identifying lesions of the head, neck, chest, retroperitoneal spaces, liver, spleen, intraabdominal and intrathoracic lymph nodes, kidneys, pelvis, and mediastinum. CT or ultrasound-guided aspiration or biopsy of suspicious lesions has reduced the need for exploratory laparotomy or thoracotomy. MRI is particularly useful for detecting osteomyelitis or myositis if there is concern about a specific limb. Diagnostic imaging can be very helpful in confirming or evaluating a suspected diagnosis; in the case of CT scans, the child is exposed to large amounts of radiation.
Biopsy is occasionally helpful in establishing a diagnosis of FUO. Bronchoscopy, laparoscopy, mediastinoscopy, and GI endoscopy can provide direct visualization and biopsy material when organ-specific manifestations are present. When employing any of the more-invasive testing procedures, the risk:benefit ratio for the patient must always be taken into consideration before proceeding further.

**Management**
The ultimate treatment of FUO is tailored to the underlying diagnosis. Fever and infection in children are not synonymous; antimicrobial agents should not be used as antipyretics, and empirical trials of medication should generally be avoided. An exception may be the use of antituberculous treatment in critically ill children with suspected disseminated tuberculosis. Empirical trials of other antimicrobial agents may be dangerous and can obscure the diagnosis of infective endocarditis, meningitis, parameningeal infection, or osteomyelitis. After a complete evaluation, antipyretics may be indicated to control fever associated with adverse symptoms.

**Prognosis**
Children with FUO have a better prognosis than do adults. The outcome in a child depends on the primary disease process, which is usually an atypical presentation of a common childhood illness. In many cases, no diagnosis can be established and fever abates spontaneously. In as many as 25% of children in whom fever persists, the cause of the fever remains unclear, even after thorough evaluation.

*Bibliography is available at Expert Consult.*
Infection and disease develop when the host immune system fails to adequately protect against potential pathogens. In individuals with an intact immune system, infection occurs in the setting of naiveté to the microbe and absence or inadequate preexisting microbe-specific immunity or when protective barriers of the body such as the skin have been breached. Healthy children are able to meet the challenge of most infectious agents with an immunologic armamentarium capable of preventing significant disease. Once an infection begins to develop, an array of immune responses is set into action to control the disease and prevent it from reappearing. In contrast, immunocompromised children might not have this same capability. Depending on the level and type of immune defect, the affected child might not be able to contain the pathogen or to develop an appropriate immune response to prevent recurrence (see Chapter 122).

General practitioners are likely to see children with abnormal immune systems in their practices because increasing numbers of children survive with primary immunodeficiencies or receive immunosuppressive therapy for treatment of malignancy, autoimmune disorders, or transplantation.

**Primary immunodeficiencies** are compromised states that result from genetic defects affecting 1 or more arms of the immune system (Table 178-1). Acquired, or secondary, immunodeficiencies may result from infection (e.g., infection with HIV), from malignancy, or as an adverse effect of immunomodulating or immunosuppressing medications. Such immunosuppressing medications include medications that affect T cells (steroids, calcineurin inhibitors, tumor necrosis factor inhibitors, and chemotherapy), neutrophils (myelosuppressive agents, idiosyncratic or immune-mediated neutropenia), specific immune regulatory cells (tumor necrosis factor blockers, interleukin-2 inhibitors), or all immune cells (chemotherapy). Perturbations of the mucosal and skin barriers or normal microbial flora can also be characterized as secondary immunodeficiencies, predisposing the host open to infections, if only for a temporary period.

The major pathogens causing infections among immunocompetent hosts are also the main pathogens responsible for infections among children with immunodeficiencies. In addition, less-virulent organisms, including normal skin flora, commensal bacteria of the oral pharynx or gastrointestinal tract, environmental fungi, and common community viruses of low-level pathogenicity, can cause severe, life-threatening illnesses in immunocompromised patients (Table 178-2). For this reason, close communication with the diagnostic laboratory is critical so that the laboratory does not disregard normal flora and organisms normally considered to be contaminants as being unimportant.

### 178.1 Infections Occurring with Primary Immunodeficiencies

**Marian G. Michaels and Michael Green**

More than 120 genes have been identified, accounting for >150 different primary immunodeficiencies.

**ABNORMALITIES OF THE PHAGOCYTIC SYSTEM**

Children with abnormalities of the phagocytic and neutrophil system have problems with bacteria as well as environmental fungi. Disease manifests as recurrent infections of the skin, mucous membranes, lungs, liver, and bones. Dysfunction of this arm of the immune system can be a result of inadequate numbers, abnormal movement properties, or aberrant function of neutrophils (see Chapter 130).

**Neutropenia** is defined as an absolute neutrophil count of <1,000 cells/mm³ and can be associated with significant risk for developing severe bacterial and fungal disease, particularly when the absolute count is <500 cells/mm³ (see Chapter 127). Although acquired neutropenia secondary to bone marrow suppression from a virus or medication is common, genetic causes of neutropenia also exist. Primary congenital neutropenia most often manifests during the 1st yr of life with cellulitis, perirectal abscesses, or stomatitis from *Staphylococcus aureus* or *Pseudomonas aeruginosa*. Episodes of severe disease, including bacteremia or meningitis, are also possible. Bone marrow evaluation shows a failure of maturation of myeloid precursors. Most forms of congenital neutropenia are autosomal dominant, but some, such as Kostmann syndrome (see Chapter 127) and Shwachman-Diamond syndrome (see Chapter 469), are caused by autosomal recessive mutations. Cyclic neutropenia can be associated with autosomal dominant inheritance or de novo sporadic mutations and manifests as fixed cycles of severe neutropenia between periods of normal granulocyte numbers. Often the neutrophil count has normalized by the time the patient presents with symptoms, thus hampering the diagnosis. The cycles classically occur every 21 days (range: 14-36 days), with neutropenia lasting 3-6 days. Most often the disease is characterized by recurrent aphthous ulcers and stomatitis during the periods of neutropenia. However, life-threatening necrotizing myositis or cellulitis and systemic disease can occur, especially with *Clostridium septicum* or *Clostridium perfringens*. Many of the neutropenic syndromes respond to colony-stimulating factor.

**Leukocyte adhesion defects** are caused by defects in the β chain of integrin (CD18), which is required for the normal process of neutrophil aggregation and attachment to endothelial surfaces (see Chapter 130). In the most-severe form there is a total absence of CD18. Children with this defect can have a history of delayed cord separation and recurrent infections of the skin, oral mucosa, and genital tract beginning early in life. Ecthyma gangrenosum also occurs. Because the defect involves leukocyte migration and adherence, the neutrophil count in the peripheral blood is usually extremely elevated but pus is not found at the site of infection. Survival is usually <10 yr in the absence of hematopoietic stem cell transplantation (HSCT).

**Chronic granulomatous disease** is an inherited neutrophil dysfunction syndrome, which can be either X-linked or autosomal recessive (see Chapter 130). In addition, chronic granulomatous disease can develop in response to spontaneous mutations in the genes associated with heritable chronic granulomatous disease. Neutrophils and other myeloid cells have defects in their nicotinamide-adenine dinucleotide phosphate oxidase function, rendering them incapable of generating superoxide and thereby impairing intracellular killing. Accordingly, microbes that destroy their own hydrogen peroxide (*S. aureus*, *Serratia marcescens*, *B. cepacia*, *Nocardia* spp., *Aspergillus*) cause recurrent infections in these children. Infections have a predilection to involve the lungs, liver, and bone. In addition, these children can present with recurrent abscesses affecting the skin or perirectal region or lymph nodes. Prophylaxis with trimethoprim-sulfamethoxazole, recombinant human interferon-γ, and oral antifungal agents that have activity against *Aspergillus* spp., such as itraconazole or newer azoles, substantially reduce the incidence of severe infections. Patients with life-threatening infections are also reported to benefit from aggressive treatment with white cell transfusions in addition to antimicrobial agents directed against the specific pathogen. In addition, HSCT can be curative but because of associated risks is not routinely performed.

**DEFECTIVE SPLENIC FUNCTION, OPSONIZATION, OR COMPLEMENT ACTIVITY**

Children who have congenital asplenia or splenic dysfunction associated with polysplenia or hemoglobinopathies, such as sickle cell disease, as well as those who have undergone splenectomy, are at risk for serious infections from encapsulated bacteria and blood-borne protozoa such as *Plasmodium* and *Babesia*. Prophylaxis against bacterial
infection with penicillin should be considered for these patients, particularly children <5 yr of age. The most common causative organisms include *S. pneumoniae, H. influenzae* type b, and *Salmonella*, which can cause sepsis, pneumonia, meningitis, and osteomyelitis. Defects in the early complement components, particularly C2 and C3, can also be associated with severe infection from these bacteria. Terminal complement defects (C3, C6, C7, C8, and C9) are associated with recurrent infections with *Neisseria*. Patients with complement deficiency also have an increased incidence of autoimmune disorders. Vaccines for *S. pneumoniae, H. influenzae* type b, and *N. meningitidis* should be administered to all children with abnormalities in opsonization or complement pathways (see Chapter 134).

**B-CELL DEFECTS (HUMORAL IMMUNODEFICIENCIES)**

Antibody deficiencies account for the majority of primary immunodeficiencies among humans (see Chapter 124). Patients with defects in the B-cell arm of the immune system fail to develop appropriate antibody responses, with abnormalities that range from complete agammaglobulinemia to isolated failure to produce antibody against a specific antigen or organism. Antibody deficiencies found in children with diseases such as X-linked agammaglobulinemia or common variable immunodeficiency predispose to infections with encapsulated organisms such as *S. pneumoniae* and *H. influenzae* type b. Other bacteria can also be problematic in these children (see Table 178-2). Even though most other classes of microbes do not cause problems for these patients, some notable exceptions exist. Rotavirus can lead to chronic diarrhea, and enteroviruses can disseminate and cause a chronic meningoencephalitis syndrome in these patients. Paralytic polio has developed after immunization with live polio vaccine. Protozoan infections such as giardiasis can be severe and persistent. Children with B-cell defects can develop bronchiectasis over time following chronic or recurrent pulmonary infections.

Children with antibody deficiencies are usually asymptomatic until 5-6 mo of age, when maternally derived antibody levels begin to wane. These children begin to develop recurrent episodes of otitis media, bronchitis, pneumonia, bacteremia, and meningitis. Many of these infections respond quickly to antibiotics, which can delay the recognition of antibody deficiency. Children who require myringotomy tube placement before 2 yr of age because of recurrent episodes of otitis media (≥3 episodes within 6 mo, or ≥4 episodes within 12 mo) should be considered for screening measurement of immunoglobulin levels.

The significance and impact of specific immunoglobulin (Ig) G subclass deficiencies is less-well understood and remains controversial. Deficiencies of specific IgG subclasses were first noted in healthy adult blood donors in whom no increased susceptibility to infections was documented. However, others have identified specific IgG deficiencies to be associated with a predisposition to recurrent bacterial sinopulmonary infection, bacteremia, meningitis, osteomyelitis, and pyoderma. Deficiency of subclass IgG2 is associated with poor antibody responses at the mucosal membranes (see Chapter 124). Even though most patients have no increased risk for infections, some have mild to moderate disease at sites of mucosal barriers. Accordingly, recurrent sinopulmonary infection and gastrointestinal disease are the major clinical manifestations. These patients also have an increased incidence of allergies and autoimmune disorders compared with the normal population.

Selective IgA deficiency leads to a lack of production of secretory antibody at the mucosal membranes (see Chapter 124). Even though most patients have no increased risk for infections, some have mild to moderate disease at sites of mucosal barriers. Accordingly, recurrent sinopulmonary infection and gastrointestinal disease are the major clinical manifestations. These patients also have an increased incidence of allergies and autoimmune disorders compared with the normal population.

Hyper-IgM syndrome is caused by a defect in the CD40 ligand on the T cell and is associated with a deficiency in the production of IgG and IgA antibody (see Chapter 124). In addition, recurrent neutropenia, hemolytic anemia, or aplastic anemia can be present. Similar to patients with agammaglobulinemia, these patients are at risk for bacterial sinopulmonary infections, *Pneumocystis jiroveci* pneumonia (PCP), and Cryptosporidium intestinal infection.

Replacement of antibody with immunoglobulin, administered intravenously every 3–4 wk or weekly, using a subcutaneous formulation, has been the mainstay of treatment for most of the primary IgG antibody deficiencies. Immunoglobulin replacement is not advocated for IgA deficiency, because it does not correct the defect. Prophylaxis with specific antibiotic regimens is controversial and should be individualized for patients who do not respond to immunoglobulin replacement.

**T-CELL DEFECTS (CELL-MEDIATED IMMUNODEFICIENCIES)**

Children with primary cell-mediated immunodeficiencies, either isolated or more commonly in combination with B-cell defects, present early in life and are susceptible to viral, fungal, and protozoan infections. Clinical manifestations include chronic diarrhea, mucocutaneous candidiasis, and recurrent pneumonia, rhinitis, and otitis media. In thymic hypoplasia (DiGeorge syndrome), hypoplasia or aplasia of the thymus and parathyroid glands occurs during fetal development in association with the presence of other congenital abnormalities. Hypocalcemia and cardiac anomalies are usually the presenting features of DiGeorge syndrome, which should prompt evaluation of the T-cell system. Chronic mucocutaneous candidiasis is a rare immunodeficiency associated primarily with T-cell dysfunction (see Chapter 125). These patients might not demonstrate delayed hypersensitivity to skin tests for *Candida* antigen despite having chronic superficial infection with yeast, but they do not appear to be at increased risk for systemic yeast infections. Endocrinopathies are commonly associated with chronic mucocutaneous candidiasis.

**COMBINED B-CELL AND T-CELL DEFECTS**

Patients with defects in both the T-cell and B-cell components of the immune system have variable manifestations depending on the extent of the defect (see Chapter 126). Complete or almost complete immunodeficiency is found with severe combined immunodeficiency disorder, whereas partial defects can be present in such states as ataxia-telangiectasia, Wiskott-Aldrich syndrome, hyper-IgE syndrome, and X-linked lymphoproliferative disorder. Rather than 1 disorder, it is now recognized that severe combined immunodeficiency disorder represents a heterogeneous group of genetic defects that leave the infant globally immune deficient and present in the 1st 6 mo of life with recurrent and typically severe infections caused by a variety of bacteria, fungi, and viruses. Failure to thrive, chronic diarrhea, mucocutaneous or systemic candidiasis, PCP, or cytomegalovirus (CMV) infections are common early in life. Passive maternal antibody is relatively protective against the bacterial pathogens during the 1st few mo of life, but thereafter patients are susceptible to both Gram-positive and Gram-negative organisms. Exposure to live virus vaccines can also lead to disseminated disease; accordingly, the use of live vaccines (including rotavirus vaccine) is contraindicated in patients with suspected or proven severe combined immunodeficiency disorder. Without stem cell transplantation or gene therapy, most affected children succumb to opportunistic infections within the 1st yr of life.

Children with ataxia-telangiectasia develop late onset of recurrent sinopulmonary infections from both bacteria and respiratory viruses. In addition, these children experience an increased incidence of malignancies. Wiskott-Aldrich syndrome is an X-linked recessive disease associated with eczema, thrombocytopenia, a reduced number of CD3 lymphocytes, moderately suppressed mitogen responses, and impaired antibody response to polysaccharide antigens. Accordingly, infections with *S. pneumoniae* or *H. influenzae* type b and PCP are common. Children with hyper-IgE syndrome have markedly elevated levels of IgE and present with recurrent episodes of *S. aureus* abscesses of the skin, lungs, and musculoskeletal system. Although the antibody abnormality is notable, these patients also have marked eosinophilia and poor cell-mediated responses to neoantigens and are also at increased risk for fungal infections.

178.2 Infections Occurring with Acquired Immunodeficiencies
Marian G. Michaels and Michael Green

Immunodeficiencies can be secondarily acquired as a result of infections or as a consequence of other underlying disorders such as malignancy, cystic fibrosis, diabetes mellitus, sickle cell disease, or malnutrition. Immunosuppressive medications used to prevent rejection after organ transplantation, to prevent graft-versus-host disease after stem cell transplantation (see Chapter 137), or to treat malignancies can also leave the host vulnerable to infections. Similarly, medications used to control rheumatologic or other autoimmune diseases may be associated with an increased risk for developing infection. Any process that disrupts the normal mucosal and skin barriers (e.g., burns, surgery, indwelling catheters) can lead to an increased risk for infection.

ACQUIRED IMMUNODEFICIENCY FROM INFECTIOUS AGENTS

Infection with HIV, the causative agent of AIDS, is the most important infectious cause of acquired immunodeficiency (see Chapter 276). Left untreated, HIV infection has profound effects on many parts of the immune system but in particular T-cell–mediated immunity that leads to susceptibility to the same types of infections as with primary T-cell immunodeficiencies.

Other organisms can also lead to temporary alterations of the immune system. Very rarely transient neutropenia associated with community-acquired viruses can lead to significant disease with bacterial infections. Secondary infections can occur because of impaired immunity or disruption of normal mucosal immunity, as exemplified by the increased risk for pneumonia from S. pneumoniae or S. aureus following influenza infection and group A streptococcus cellulitis and fasciitis following varicella.

MALIGNANCIES

The immune systems of children with malignancies are compromised by the therapies used to treat the cancer and, at times, by direct effects of the cancer itself. The type, duration, and intensity of antineoplastic therapy remain the major risk factors for infections in these children and often affect multiple arms of the immune system. The presence of mucous membrane abnormalities, indwelling catheters, malnutrition, prolonged exposure to antibiotics, and frequent hospitalizations adds to the risk for infection in these children.

Even though several arms of the immune system can be affected, the major abnormality predisposing to infection in children with cancer is neutropenia. The depth and duration of neutropenia are the primary predictors of the risk of infection in children being treated for cancer. Patients are at particular risk for bacterial and fungal infections if the absolute neutrophil count decreases to <500 cells/mm³ and the risk is highest in those anticipated to have counts <100 cells/mm³. Counts of >500 cells/mm³ but <1,000 cells/mm³ incur some increased risk for infection but not nearly as great. The lack of neutrophils can lead to a loss of inflammatory response, limiting the ability to localize sites of infection and potentially leaving fever as the only manifestation of infection. Accordingly, the absence of physical signs and symptoms does not reliably exclude the presence of infection, resulting in the need for empirical antibiotics (Fig. 178-1). Because patients with fever and neutropenia might only have subtle signs and symptoms of infection, the presence of fever warrants a thorough physical examination with careful attention to the oropharynx, lungs, perineum and anus, skin, nail beds, and intravascular catheter insertion sites (Table 178-3). A comprehensive laboratory evaluation, including a complete blood cell count, serum creatinine, blood urea nitrogen, and serum transaminases, should be obtained. Blood cultures should be taken from each port of any central venous catheter. Consideration should also be given to obtaining a peripheral venous sample for blood culture, especially in children with 1 or more positive cultures from a central venous catheter, facilitating localization of the source of the infection. Other microbiologic studies should be done if there are associated clinical symptoms, including nasal aspirate for viruses in patients with upper respiratory findings; stool for rotavirus in the winter months and for C. difficile toxin in patients with diarrhea; urinalysis and culture in young children or in older patients with symptoms of urgency, frequency, dysuria, or hematuria; and biopsy and culture of cutaneous lesions. Chest radiographs should be obtained in any patient with lower respiratory tract symptoms, although pulmonary infiltrates may be absent in children with severe neutropenia. Sinus films should be obtained for children >2 yr of age if rhinorrhea is prolonged. Abdominal CT scans should also be considered in children with profound neutropenia and abdominal pain to evaluate for the presence of typhilitis. Chest CT scan and galactomannan testing should be considered for children not responding to broad-spectrum antibiotics who have continued fever and neutropenia for longer than 96 hr. Biopsies for cytology, Gram stain, and culture should be considered if abnormalities are found during endoscopic procedures or if lung nodules are identified radiographically.

Before the routine institution of empirical antimicrobial therapy for fever and neutropenia, 75% of children with fever and neutropenia were ultimately found to have a documented site of infection, suggesting that most children with fever and neutropenia will have an underlying infection (see Table 178-3). Currently, Gram-positive cocci are the most common pathogens identified in these patients; however, Gram-negative organisms such as P. aeruginosa, E. coli, and Klebsiella can cause life-threatening infection and must be considered in the empirical treatment regimen. Other multidrug-resistant Enterobacteriaceae are increasingly recovered in these children. Although coagulase-negative staphylococci often cause infections in these...
children in association with central venous catheters, these infections are typically indolent, and a short delay in treatment usually does not lead to a detrimental outcome. Other Gram-positive bacteria, such as *S. aureus* and *S. pneumoniae*, can cause more fulminant disease and require prompt institution of therapy. Viridans streptococci are important potential pathogens in patients with the oral mucositis that is often associated with use of cytarabine and in patients who experience selective pressure from treatment with certain antibiotics such as quinolones. Infection caused by this organism can present as acute septic shock syndrome. Patients with prolonged neutropenia are at increased risk for opportunistic fungal infections, with *Candida* spp. and *Aspergillus* spp. being the most commonly identified fungi. Other fungi that can cause serious disease in these children include *Mucor* spp., *Fusarium* spp., and dematiaceous molds.

**FEVER AND NEUTROPENIA**

The use of empiric antimicrobial treatment as part of the management of fever and neutropenia decreases the risk of progression to sepsis, septic shock, acute respiratory distress syndrome, organ dysfunction, and death. In 2010, the Infectious Diseases Society of America updated a comprehensive guideline for the use of antimicrobial agents in neutropenic children and adults with cancer (see Fig. 178-1).

First-line antimicrobial therapy should take into consideration the types of microbes anticipated and the local resistance patterns encountered at each institution as well as the level of risk for severe infection associated with a given patient. In addition, antibiotic choices may be limited by specific circumstances, such as the presence of drug allergy and renal or hepatic dysfunction. The empirical use of oral antibiotics has been shown to be safe in some low-risk adults who have no evidence of bacterial focus or signs of significant illness (rigors, hypotension, mental status changes) and for whom a quick recovery of the bone marrow is anticipated. Guidelines for the management of fever and neutropenia in children with cancer and/or undergoing HSCT, which were published on 2012, conclude that the use of oral antimicrobial therapy as either initial or stepdown therapy can be considered in low-risk children who can tolerate oral antibiotics and in whom careful monitoring can be ensured. However, the authors of this guideline point out that oral medication use may present major challenges in children, including availability of liquid formulations of appropriate antibiotics, cooperation of young children, and presence of mucositis potentially interfering with absorption. Accordingly, decisions to implement this approach should be reserved for a very select subset of these children presenting with fever and neutropenia.

The decision to initially use intravenous monotherapy vs an expanded regimen of antibiotics depends on the severity of illness of the patient, history of previous colonization with resistant organisms, and obvious presence of catheter-related infection. Vancomycin should be added to the empiric initial regimen if the patient has hypotension or other evidence of septic shock, an obvious catheter-related infection, or a history of colonization with methicillin-resistant *S. aureus*, or if the patient is at high risk for viridans streptococci (severe mucositis, acute myelogenous leukemia, or prior use of quinolone prophylaxis). Monotherapy can be considered with cefepime, imipenem/cilastatin, meropenem, piperacillin-tazobactam, or ticarcillin-clavulanic acid. Cefazidime should not be used as monotherapy if concern exists for Gram-positive organisms or resistant Gram-negative bacteria. The addition of a 2nd Gram-negative bacterial agent for empiric therapy can be considered in patients who are clinically unstable when resistant organisms are suspected.

Regardless of the regimen chosen initially, it is critical to carefully and continually evaluate the patient for response to therapy, development of secondary infections, and adverse effects. Management recommendations for these children are evolving. Based upon the 2012 published guidelines, patients who have negative blood cultures at 48 hr, who have been afebrile for at least 24 hr, and who have evidence of bone marrow recovery (absolute neutrophil counts of >100 cells/mm³) can have antibiotics discontinued. However, if symptoms persist or evolve, intravenous antibiotics should be continued. Continuation of antibiotics in children whose fever has abated and who are clinically well but continue to have depression of neutrophils is more controversial. The 2012 pediatric guidelines advocate pediatric guidelines advocate discontinuing antibiotics in low-risk patients at 72 hr for patients who have negative blood cultures and who have been afebrile for at least 24 hr regardless of bone marrow recovery, as long as careful follow-up is ensured. In contrast, others continue to advocate for continuing antibiotics in this circumstance to prevent recurrence of fever.

Patients without an identified etiology but with persistent fever should be reasessed after 3-5 days. Those remaining clinically well may continue on the same regimen, although consideration should be given to discontinuing vancomycin or double Gram-negative bacterial coverage if they were included initially. Patients who remain febrile with clinical progression warrant the addition of vancomycin or double Gram-negative bacterial coverage if they were included initially. Patients who remain febrile with clinical progression warrant the addition of vancomycin if it was not included initially and certain risk factors exist; clinicians should also consider changing the empirical antibacterial regimen to cover the potential presence of antimicrobial resistance in these children. If fever persists for longer than 96 hr, the addition of an antifungal agent with antimold activity should be considered, particularly for those at high risk for invasive fungal infection (those with acute myelogenous leukemia or relapsed acute lymphocytic leukemia or who are receiving highly myelosuppressive chemotherapies for other cancers or with allogeneic HSCT). Medications, including liposomal amphotericin products or caspofungin, have been studied in children; voriconazole itraconazole, posaconazole, and micafungin have all been successfully used in adults. Studies comparing caspofungin to liposomal amphotericin for children with malignancies and fever and neutropenia showed caspofungin to be noninferior. The use of antiviral agents in fever and neutropenia is not warranted without specific evidence of viral disease. Active herpes simplex or varicella-zoster lesions merit treatment to decrease the time of healing; even if these lesions are not the source of fever, they are potential portals of entry.

The use of hematopoietic growth factors shortens the duration of neutropenia but has not been proved to reduce morbidity or mortality. Accordingly, the 2010 recommendations from the Infectious Diseases Society of America do not endorse the routine use of hematopoietic growth factors in patients with established fever and neutropenia, although the recommendations do note that hematopoietic growth factors can be considered as prophylaxis in those with neutropenia who have a high risk for fever. Infections occur in children with cancer even without neutropenia. Most often these infections are viral in etiology. However, P. jiroveci can cause pneumonia regardless of the neutrophil count. Prophylaxis with trimethoprim-sulfamethoxazole against PCP is an effective preventive strategy and should be provided to all children undergoing active treatment for malignancy (see Chapter 244). Environmental fungi such as Cryptococcus, Histoplasma, and Coccidioides can also cause disease. Toxoplasma gondii is an uncommon but occasional pathogen in children with cancer. Infections encountered in healthy children (S. pneumoniae, group A Streptococcus) can cause disease in children with cancer regardless of the granulocyte count.

**TRANSPANTATION**

Transplantation of hematopoietic stem cells and solid organs (including heart, liver, kidney, lungs, pancreas, and intestines) is increasingly used as therapy for a variety of disorders. Children undergoing transplantation are at risk for infections caused by many of the same microbial agents that cause disease in children with primary immunodeficiencies. Although the types of infections after transplantation are similar in general among all recipients of these procedures, some differences exist between patients depending on the type of transplantation performed, the type and amount of immunosuppression given, and the child’s preexisting immunity to specific pathogens.

**Stem Cell Transplantation**

Infections following HSCT can be classified as occurring during the pretransplantation period, preengraftment period (0-30 days after transplantation), postengraftment period (30-100 days), or late posttransplantation period (>100 days). Specific defects in host defenses predisposing to infection vary within each of these periods (Table 178-4). Neutropenia and abnormalities in cell-mediated and humoral immune function occur predictably during specific periods of time following transplantation. In contrast, breaches of anatomic barriers caused by indwelling catheters and mucositis secondary to radiation or chemotherapy create defects in host defenses that may be present any time following transplantation.

**Pretransplantation Period**

Children come to HSCT with a heterogeneous history of underlying diseases, chemotherapy exposure, degree of immunosuppression, and previous infections. Approximately 12% of all infections among adult HSCT recipients occur during the pretransplantation period. These infections are often caused by aerobic Gram-negative bacilli and manifest as localized infections of the skin, soft tissue, and urinary tract. Importantly, the development of infection during this period does not delay or adversely affect the success of engraftment.

**Preengraftment Period**

**Bacterial infections** predominate in the preengraftment period (0-30 days). Bacteremia is the most common documented infection and occurs as often as 50% of all HSCT recipients within the first 30 days following transplantation. Bacteremia is typically associated with the presence of either mucositis or an indwelling catheter, but may also be seen with pneumococci. Similarly, more than 40% of children undergoing HSCT experienced 1 or more infections in the preengraftment period. Gram-positive cocci, Gram-negative bacilli, yeast, and, less commonly, other fungi cause infection during this period. Aspergillus has been identified in 4-20% of HSCT recipients, most often after 3 wk of neutropenia. Infections caused by the emerging fungal pathogens Fusarium and Pseudallescheria boydii are associated with the prolonged neutropenia during the preengraftment period.

**Viral infections** also occur during the preengraftment period. Among adults, reactivation of herpes simplex virus is the most common viral disease observed, but this is less common among children, which is likely related to absence of the virus in the recipient before HSCT. A history of herpes simplex infection or seropositivity indicates the need for prophylaxis. Nosocomial exposure to community-acquired viral pathogens, including respiratory syncytial virus (RSV), influenza virus, adenovirus, and rotavirus, represents another important source of infection during this period. There is growing evidence that community-acquired viruses cause increased morbidity and mortality for HSCT recipients.
recipients during this period. Adenovirus is a particularly important viral pathogen that can occur early, although it typically presents after engraftment.

**Postengraftment Period**

The predominant defect in host defenses in the postengraftment period is altered cell-mediated immunity. Accordingly, organisms historically categorized as opportunistic pathogens predominate during this period. The risk is especially accentuated 50-100 days after transplantation when host immunity is lost and donor immunity is not yet established. *P. jiroveci* presents during this period if patients are not maintained on appropriate prophylaxis. Reactivation of *T. gondii*, a rare cause of disease among HSCT recipients, can also occur after engraftment. Hepatosplenic candidiasis often presents during the postengraftment period, although seeding likely occurred during the neutropenic phase.

CMV is an important cause of morbidity and mortality among HSCT recipients. Unlike patients undergoing solid-organ transplantation where primary infection from the donor causes the greatest harm, CMV reactivation in an HSCT recipient whose donor is naïve to the virus can cause severe disease. Disease risk from CMV after HSCT is also increased in recipients of matched unrelated T cell-depleted transplants and those who suffer from graft-versus-host disease. Adenovirus is another important viral pathogen; it has been recovered from up to 5% of adult and pediatric HSCT recipients and causes invasive disease in approximately 20% of cases. Children receiving matched unrelated donor organs or unrelated cord blood cell transplants have an incidence of adenovirus infection as high as 14% during this early postengraftment period. Polyomaviruses such as BK virus have been increasingly recognized as a cause of renal dysfunction and hemorrhagic cystitis after bone marrow transplantation. Infections with other herpesviruses (Epstein-Barr virus [EBV] and human herpesvirus 6), as well as community-acquired pathogens, are associated with excess morbidity and mortality during this period, similar to the preengraftment period.

**Late Posttransplantation Period**

Infection is unusual after 100 days in the absence of chronic graft-versus-host disease. However, the presence of chronic graft-versus-host disease significantly affects anatomic barriers and is associated with defects in humoral, splenic, and cell-mediated immune function (see Chapter 137). Viral infections, including primary infection with or reactivation of varicella-zoster virus, are responsible for more than 40% of infections during this period. Bacterial infections, particularly of the upper and lower respiratory tract, account for approximately 30% of infections. These may be associated with deficiencies in immunoglobulin production, especially IgG. Fungal infections account for <20% of confirmed infections during the late posttransplantation period.

**Solid-Organ Transplantation**

Factors predisposing to infection after organ transplantation include those that either existed before transplantation or are secondary to intraoperative events or posttransplantation therapies (Table 178-5). Some of these additional risks cannot be prevented, and some risks acquired during or after the operation depend on decisions or actions of members of the transplant team. Similar to other children who have undergone surgical procedures, surgical site infections are a frequent cause of infection early after transplantation. Beyond this, the need for immunosuppressive agents to prevent rejection is the major factor predisposing to infection following transplantation. Despite efforts to optimize immunosuppressive regimens to prevent or treat rejection with minimal impairment of immunity, all current regimens interfere with the ability of the immune system to prevent infection. The primary target of the majority of these immunosuppressive agents is the cell-mediated immune system, but regimens can and do impair many other aspects of the transplant recipient's immune system as well.

**Timing**

The timing of specific types of infections is generally predictable, regardless of which organ is transplanted (Table 178-6). Infectious complications typically develop in 1 of 3 time intervals: early (0-30 days after transplantation), intermediate (30-180 days), and late (>180 days); most infections present in the 1st 180 days after transplantation. Table 178-6 should be used as a general guideline to the types of infections encountered but may be modified with the introduction of newer immunosuppressive therapies and by the use of prophylaxis.

Early infections are usually the result of a complication of the transplant surgery itself, the unexpected acquisition of a bacterial or fungal pathogen from the donor, or the presence of an indwelling catheter. In contrast, infections during the intermediate period typically result from a complication of the immunosuppression, which tends to be at its greatest intensity during the 1st 6 mo following transplantation. This is the period of greatest risk for infections caused by opportunistic pathogens such as CMV, EBV, and *P. jiroveci*. Anatomic abnormalities, such as bronchial stenosis and biliary stenosis, that develop as a consequence of the transplant surgery can also predispose to recurrent infection in this period.

Infections developing late after transplantation typically result as a consequence of uncorrected anatomic abnormalities, chronic rejection, or exposure to community-acquired pathogens. Acquisition of infection from community-acquired pathogens such as RSV can result in severe infection secondary to the immunocompromised state of the transplant recipient during the early and intermediate periods. Compared with the earlier periods, community-acquired infections in the late period are usually benign, because immunosuppression is typically maintained at significantly lower levels. However, certain pathogens such as varicella-zoster virus and EBV may be associated with severe disease even at this late period.

**Bacterial and Fungal Infections**

Although there are important graft-specific considerations for bacterial and fungal infections following transplantation, some principles are generally applicable to all transplant recipients. Bacterial and fungal infections following organ transplantation are usually a direct consequence of the surgery, a breach in an anatomic barrier, the presence of a foreign body, or an abnormal anatomic narrowing or obstruction. With the exception of infections related to the use of indwelling catheters, sites of bacterial infection tend to occur at or near the transplanted organ. Infections following abdominal transplantation (liver, intestine, or renal) usually occur in the abdomen or at the surgical wound. The pathogens are typically enteric Gram-negative bacteria, *Enterococcus*, and occasionally *Candida*. Infections following thoracic transplantation (heart, lung) usually occur in the lower respiratory tract or at the surgical wound. Pathogens associated with these infections include *S. aureus* and Gram-negative bacteria.
Patients undergoing lung transplantation for cystic fibrosis experience a particularly high rate of infectious complications, because they are often colonized with *P. aeruginosa* or *Aspergillus* before transplantation. Even though the infected lungs are removed, the sinuses and upper airways remain colonized with these pathogens, and subsequent reinfection of the transplanted lungs can occur. Children receiving organ transplants are often hospitalized for long periods and receive many antibiotics; thus, recovery of bacteria with multiple antibiotic resistance patterns is common after all types of organ transplantation. Infections caused by *Aspergillus* are less common but occur after all types of organ transplantation and are associated with high rates of morbidity and mortality.

### Table 178-6 Timing of Infectious Complications Following Solid-Organ Transplantation

**EARLY PERIOD (0-30 DAYS)**  
**Bacterial Infections**  
- Gram-negative enteric bacilli  
- Small bowel, liver, neonatal heart  
*Pseudomonas, Burkholderia, Stenotrophomonas, Alcaligenes*  
- Cystic fibrosis lung  
- Gram-positive organisms  
- All transplant types  
**Fungal Infections**  
- All transplant types  
**Viral Infections**  
- Herpes simplex virus  
- All transplant types  
- Nosocomial respiratory viruses  
- All transplant types  

**MIDDLE PERIOD (1-6 MO)**  
**Viral Infections**  
- Cytomegalovirus  
- All transplant types  
- Seronegative recipient of seropositive donor  
- Epstein-Barr virus  
- All transplant types (small bowel highest risk group)  
- Seronegative recipient  
- Varicella-zoster virus  
- All transplant types  
- Opportunistic infections  
*Pneumocystis jiroveci*  
- All transplant types  
- Toxoplasma gondii  
- Seronegative recipient of cardiac transplant from a seropositive donor  
**Bacterial Infections**  
*Pseudomonas, Burkholderia, Stenotrophomonas, Alcaligenes*  
- Cystic fibrosis lung  
- Gram-negative enteric bacilli  
- Small bowel  

**LATE PERIOD (>6 MO)**  
**Viral Infections**  
- Epstein-Barr virus  
- All transplant types, but less risk than middle period  
- Varicella-zoster virus  
- All transplant types  
- Community-acquired viral infections  
- All transplant types  
**Bacterial Infections**  
*Pseudomonas, Burkholderia, Stenotrophomonas, Alcaligenes*  
- Cystic fibrosis lung  
- Lung transplants with chronic rejection  
- Gram-negative bacillary bacteremia  
- Small bowel  
**Fungal Infections**  
- *Aspergillus*  
- Lung transplants with chronic rejection

### Viral Infections

Viral pathogens, especially herpesviruses, are a major source of morbidity and mortality following solid organ transplantation. In addition, BK virus is a major cause of renal disease following kidney transplantation. The patterns of disease associated with individual viral pathogens are generally similar among all organ transplant recipients. However, the incidence, mode of presentation, and severity differ according to type of organ transplanted and, for many viral pathogens, pretransplant serologic status of the recipient.

Viral pathogens can be generally categorized as latent pathogens, which cause infection through reactivation in the host or via acquisition from the donor (e.g., CMV and EBV), or as community-acquired viruses (e.g., RSV). For CMV and EBV, primary infection occurring after transplantation is associated with the greatest degree of morbidity and mortality. The highest risk is seen in a naïve host who receives an organ from a donor who previously was infected with 1 of these viruses. This “mismatched” state is frequently associated with severe disease. However, even if the donor is negative for CMV and EBV, primary infection can be acquired from a close contact or via blood products. Secondary infections (reactivation of a latent strain within the host or superinfection with a new strain) tend to result in milder illness unless the patient is highly immunosuppressed, which can occur in the setting of treatment of significant rejection.

CMV is one of the most commonly recognized transplant viral pathogens. Disease from CMV has decreased significantly with the use of preventive strategies including antiviral prophylaxis as well as viral load monitoring to inform preemptive antiviral therapy. Clinical manifestations of CMV disease can range from a syndrome of fatigue and fever to disseminated disease that most often affects the liver, lungs, and gastrointestinal tract.

Infection caused by EBV is another important complication of solid-organ transplantation. Clinical symptoms range from a mild mononucleosis syndrome to disseminated posttransplant lymphoproliferative disorder. Posttransplant lymphoproliferative disorder is more common among children than adults because primary EBV infection in the immunosuppressed host is more likely to lead to uncontrolled proliferative disorders, including posttransplant lymphoma.

Other viruses, such as adenovirus, have the capacity to be donor associated, but appear to be less common. The unexpected development of donor-associated viral pathogens, including hepatitis B virus, hepatitis C virus, and HIV, is rare today owing to intensive donor screening.

Community-acquired viruses, including those associated with respiratory tract infection (RSV, influenza virus, adenovirus, and parainfluenza) and gastrointestinal infection (enteroviruses, rotavirus), can cause important disease in children following organ transplantation. In general, risk factors for more-severe infection include young age, acquisition of infection early after transplantation, and augmented immune suppression. Infection in the absence of these risk factors typically results in a clinical illness that is comparable with that seen in immunocompetent children. However, some community-acquired viruses, such as adenovirus, can be associated with graft dysfunction even when acquired late after transplantation.

### Opportunistic Pathogens

Children undergoing solid-organ transplantation are also at risk for symptomatic infections from pathogens that do not usually cause clinical disease in immunocompetent hosts. Although these most commonly present in the intermediate period, these infections can also occur late in patients requiring prolonged and high levels of immunosuppression. *P. jiroveci* is a well-recognized cause of pneumonia following solid-organ transplantation, although routine prophylaxis has essentially eliminated this problem. *T. gondii* can complicate cardiac transplantsations because of tropism of the organism for cardiac muscle and risk for donor transmission; less commonly it complicates other types of organ transplantation.

Bibliography
Infections cannot be completely prevented in children who have defects in one or more arms of their immune system, although some measures can decrease the risks for infection. Replacement immunoglobulin is a benefit to children with primary B-cell deficiencies. Interferon-γ, trimethoprim-sulfamethoxazole, and oral antifungal agents reduce the number of infections occurring in children with chronic granulomatous disease. Children who have depressed cellular immunity resulting from primary diseases, advanced HIV infection, or immunosuppressive medications benefit from prophylaxis against *P. jiroveci*. Immunizations prevent many infections and are particularly important for children with compromised immune systems. When possible, immunizations should be administered before any treatment that would compromise the child's immune system.

Although immunodeficient children are a heterogeneous group, some principles of prevention are generally applicable. The use of inactivated vaccines does not lead to an increased risk for adverse effects, although their efficacy may be reduced due to an impaired immune response. In most cases, children with immunodeficiencies should receive all of the recommended inactivated vaccines. Live-attenuated virus vaccinations can cause disease in some children with immunologic defects, and therefore alternative immunizations should be used whenever possible, such as inactivated influenza vaccine rather than live virus attenuated influenza vaccine. In general, live virus vaccines should not be used in children with primary T-cell abnormalities; efforts should be made to ensure that close contacts are all immunized to decrease the risk of exposure. In some instances in which wild-type viral infection can be severe, immunizations, even with live virus vaccine, are warranted in the immunosuppressed child. For example, children with HIV infection and a CD4 percentage of >15% should receive vaccinations against measles and varicella. Some vaccines should be given to children with immunodeficiencies in addition to routine vaccinations. As an example, children with asplenia or splenic dysfunction should receive meningococcal vaccine and both the polysaccharide pneumococcal vaccine and the conjugate pneumococcal vaccine. Influenza vaccination is recommended for immunocompromised children as well as all household contacts to minimize risk for transmission to the immunocompromised child.

Bibliography
Use of implanted synthetic and prosthetic devices has revolutionized pediatric practice by providing long-term venous access, limb-salvage surgery, and successful treatment of hydrocephalus, urinary retention, and renal failure. However, infectious complications of these devices remain a major concern. These infections are related to the development of biofilms, organized communities of microorganisms protected from the immune system and antimicrobial therapy, on the device surface. A number of factors are important to the development of infection, including the host susceptibility, device composition, duration of implantation, and exposure to colonizing organisms.

**INTRAVASCULAR ACCESS DEVICES**

Intravascular access devices range from short, stainless steel needles or plastic cannulae inserted for brief periods to multilumen implantable synthetic plastic catheters that are expected to remain in use for years. Infectious complications include local skin and soft tissue infections such as exit site, tunnel, and device-pocket infections, and catheter-related bloodstream infections (CRBSIs). The use of central venous devices has improved the quality of life of high-risk patients but has also increased the risk of infection.

**Catheter Types**

Short-term peripheral cannulae are most commonly used in pediatric patients, and infectious complications occur infrequently. The rate of peripheral CRBSIs in children is <0.15%. Patient age <1 yr, duration of use for longer than 144 hr, and some infusates are associated with increased risk for catheter-related infection. Catheter-associated phlebitis is more common (1-6%) but is rarely infective and can be treated conservatively.

Central venous catheters (CVCs), which terminate in a central vein such as the superior vena cava or inferior vena cava, are widely used in both adults and pediatric patients and are responsible for the majority of catheter-related infections. These catheters are commonly used in critically ill patients, including neonates, who have many other risk factors for nosocomial infection. Patients in an intensive care unit with a CVC in place have a 5-fold greater risk for developing a nosocomial bloodstream infection than those without.

The use of peripherally inserted central catheters, which are inserted into a peripheral vein and terminate in a central vein, has increased in pediatric patients. Infection rates seem to be similar to long-term tunneled CVCs (~2/1,000 days), but other complications such as fracture, dislodgement, and occlusion are more common.

When prolonged intravenous access is required, a cuffed silicone rubber (Silastic) or polyurethane catheter may be inserted into the superior vena cava through the subclavian, cephalic, or jugular vein. The extravascular segment of the catheter passes through a subcutaneous tunnel before exiting the skin, usually on the superior aspect of the chest (Broviac or Hickman catheter). A cuff around the catheter near the exit site induces a fibrotic reaction to seal the tunnel. Totally implanted devices also include a subcutaneous reservoir or port with a self-sealing silicone septum immediately under the skin that permits repeated percutaneous needle access.

The incidence of local (exit site, tunnel, and pocket) infection with long-term catheters is 0.2-2.8/1,000 catheter-days. The incidence of Broviac or Hickman CRBSI is 0.5-11.0/1,000 catheter-days, whereas that for implantable devices is 0.3-1.8/1,000 catheter-days. The risk for CRBSI is increased among premature infants, young children, and patients receiving total parenteral nutrition.

**Catheter-Associated Skin and Soft Tissue Infection**

A number of local infections can occur in the presence of a CVC. The clinical manifestations of local infection include erythema, tenderness, and purulent discharge at the exit site or along the subcutaneous tunnel tract of the catheter. Exit-site infection denotes infection localized to the exit site, without significant tracking along the tunnel, often with purulent discharge. Tunnel-tract infection indicates infection in the subcutaneous tissues tracking along a tunneled catheter, which may also include serous or serosanguineous discharge from a draining sinus along the path. Pocket infection indicates supplicative infection of a subcutaneous pocket containing a totally implanted device. Bloodstream infection may coexist with local infection.

The diagnosis of local infection is established clinically, but a gram-stained smear and culture of any exit-site drainage should be performed to identify the microbiologic cause. The source is usually contamination by skin or gastrointestinal flora, and the most common organisms are *S. aureus*, coagulase-negative staphylococci,
P. aeruginosa, Candida spp., and mycobacteria. Green discharge is strongly suggestive of mycobacterial infection and appropriate stains and culture should be performed.

Treatment of local infection related to a short-term peripheral cannula or CVC should include device removal. Exit-site infection may resolve with device removal alone, but systemic symptoms should be managed with antimicrobial therapy as recommended below for treatment of CRBSI. In the case of long-term CVCs, exit-site infections usually respond to local care with topical or systemic antibiotics alone. However, tunnel or pocket infections require removal of the catheter and systemic antibiotic therapy in most cases. When a CVC is removed as a result of tunnel infection, the cuff should also be removed and sent for culture if possible. In cases of mycobacterial infection, wide surgical debridement of the tissues is usually required for cure.

**Catheter-Related Bloodstream Infection**

CRBSI occurs when microorganisms attached to the CVC are shed into the bloodstream leading to bacteremia. On the device, the organisms are embedded in biofilms as organized communities. Colonization may be present even in the absence of symptoms or positive cultures. Organisms may contaminate the external surface of the CVC during insertion, or the intraluminal surface through handling of the catheter hub or contaminated infusion. Most cases of CRBSI appear to be caused by intraluminal colonization, but external colonization may play a greater role in infections related to recently inserted (<30 days) catheters. Gram-positive cocci predominate, with around half of infections caused by coagulase-negative staphylococci. Gram-negative enteric bacteria are isolated in approximately 20-30% of episodes, and fungi account for 5-10% of episodes.

Fever without an identifiable focus is the most common clinical presentation of CRBSI; local soft tissue symptoms and signs are usually absent. Onset of fever or rigors during or soon after flushing of a catheter is highly suggestive of CRBSI. Symptoms and signs of complicated infection, such as septic thrombophlebitis, endocarditis, or echyma gangrenosum, may also be present.

Blood cultures collected prior to the beginning of antibiotic therapy are generally positive from both the CVC and peripheral blood. It is important not to collect cultures unless infection is suspected, as blood-culture contamination may occur and can lead to inappropriate therapy. Blood culture should be collected from at least 2 sites, preferably including all lumens of a CVC and the peripheral blood, before initiation of antibiotic therapy to help interpret positive cultures with common skin contaminants.

Tests to differentiate CRBSI from other sources of bacteremia in the presence of a CVC include culture of the catheter tip, quantitative blood cultures, or **differential time to positivity** of blood cultures drawn from different sites. Definitive diagnosis of CRBSI can be important to identify those patients who might benefit from catheter removal or adjunctive therapy. Although CVC tip culture can identify CRBSI, it precludes salvage of the catheter. The most readily available technique to confirm CRBSI without catheter removal is calculation of differential time to positivity between blood cultures drawn through a catheter and from a peripheral vein or separate lumen. During CRBSI, blood obtained through the responsible lumen will usually indicate growth at least 2-3 hr before peripheral blood or uncolonized lumens because of a higher intraluminal microorganism burden. Idential volumes of blood must be collected simultaneously from each site and a continuously monitored blood culture system is required. Specificity of this test is good (94-100%), and sensitivity is good when a peripheral blood culture is available (~90%) but poorer when comparing 2 lumens of a CVC (64%). Where available, quantitative blood culture showing at least a 3-fold higher number of organisms from central compared with peripheral blood is similarly diagnostic.

Treatment of CRBSI related to **long-term vascular access devices** (Hickman, Broviac, totally implantable devices) with systemic antibiotics is successful for many bacterial infections without removal of the device. Antibiotic therapy should be directed to the isolated pathogen and given for a total of 10-14 days from the date of blood culture clearance. Until identification and susceptibility testing are available, empiric therapy, based on local antimicrobial susceptibility data and usually including vancomycin plus an antipseudomonal aminoglycoside (e.g., gentamicin), penicillin (e.g., piperacillin-tazobactam), or cephalosporin (e.g., ceftazidime or cefepime) is indicated. An echinocandin should be initiated if fungemia is suspected. **Antibiotic lock or dwell therapy**, with administration of solutions of high concentrations of antibiotics or ethanol that remain in the catheter for up to 24 hr, might improve outcome when used as an adjuvant to systemic therapy and appear safe, but insufficient data are available to strongly recommend their use. If blood cultures remain positive after 72 hr of appropriate therapy, or if a patient deteriorates clinically, the device should be removed. Failure of CRBSI salvage therapy is very common in infections caused by S. aureus (~50%), Candida spp. (~70%), and Mycobacterium spp. (~70%), although some case reports of cure with antimicrobial lock therapy are promising. Other indications for removing a long-term catheter include severe sepsis, supplicative thrombophlebitis, and endocarditis. Prolonged therapy (4-6 wk) is indicated for persistent bacteremia or fungemia despite catheter removal. The decision to attempt catheter salvage should weigh the risk and clinical impact of persistent or relapsed infection against the risk of surgical intervention.

CRBSI may be complicated by other intravascular infections such as septic thrombophlebitis or endocarditis. Presence of these conditions may be suggested by preexisting risk factors (such as congenital heart disease), signs and symptoms, or persistent bacteremia or fungemia 72 hr after device removal and appropriate therapy. Screening for these complications in otherwise low-risk children, even those with S. aureus infection, is not recommended, as the overall frequency is low and the tests can be difficult to interpret and may lead to inappropriate therapy.

**Prevention of Infection**

Catheters should routinely be removed as soon as they are no longer needed. Although prevalence of infection increases with prolonged duration of catheter use, routine replacement of a required CVC, either at a new site or over a guidewire, results in significant morbidity and is not recommended. Optimal prevention of infections related to long-term vascular access devices includes “bundles” of interventions, including meticulous aseptic surgical insertion technique in an operating room–like environment, avoidance of bathing or swimming (except with totally implantable devices), and careful catheter care. Use of antibiotic or ethanol lock solutions, heparin with preservatives, and alcohol-impregnated caps and use of antimicrobial-impregnated or coated catheters may also be appropriate to reduce the risk for catheter-associated bloodstream infections in high-risk populations. Although the Centers for Disease Control and Prevention recommends that short-term peripheral catheters be replaced every 72-96 hr to prevent phlebitis, pediatric data do not support this practice.

**CEREBROSPINAL FLUID SHUNTS**

Cerebrospinal fluid (CSF) shunting is required for the treatment of many children with hydrocephalus. The usual procedure uses a silicone rubber device with a proximal portion inserted into the ventricle, a unidirectional valve, and a distant segment that diverts the CSF from the ventricles to either the peritoneal cavity (ventriculoperitoneal [VP] shunt) or right atrium (ventriculointerstitial [VA] shunt). The incidence of shunt infection ranges from 1-20%, with an average of 10%. The highest rates are reported in young infants, prior shunt infections, and certain etiologies of hydrocephalus. Most infections are a result of intraoperative contamination of the surgical wound by skin flora. Accordingly, coagulase-negative staphylococci are isolated in more than half of the cases. S. aureus is isolated in approximately 20% and Gram-negative bacilli in 15% of cases.

Four distinct clinical syndromes have been described: colonization of the shunt, infection associated with wound infection, distal infection with peritonitis, and infection associated with meningitis.

The most common type of infection is colonization of the shunt with symptoms that reflect shunt malfunction as opposed to frank infection. Symptoms associated with colonized VP shunts include lethargy, headache, vomiting, a full fontanel, and abdominal pain. Fever is common but may be <39°C (102.2°F). Symptoms usually occur within months of the surgical procedure. Colonization of a VA shunt results...
in more severe systemic symptoms and specific symptoms of shunt malfunction are often absent. Septic pulmonary emboli, pulmonary hypertension, and infective endocarditis are frequently reported complications of VA shunt colonization. Chronic VA shunt colonization may cause hypocomplementemic glomerulonephritis as a consequence of antigen–antibody complex deposition in the glomeruli, commonly called shunt nephritis; clinical findings include hypertension, microscopic hematuria, elevated blood urea nitrogen and serum creatinine levels, and anemia.

**Diagnosis** is by Gram stain, microscopy, biochemistry, and culture of CSF. CSF should be obtained by direct aspiration of the shunt, as CSF obtained from either lumbar or ventricular puncture is often sterile. It is unusual to observe signs of ventriculitis, and CSF findings can be only minimally abnormal. Blood culture results are usually positive in VA shunt colonization but negative in cases of VP colonization.

Wound infection presents with obvious erythema, swelling, discharge, or dehiscence along the shunt tract and most often occurs within days to weeks of the surgical procedure. *S. aureus* is the most common isolate. In addition to the physical findings, fever is common, and signs of shunt malfunction eventually ensue in most cases.

Distal infection of VP shunts with peritonitis presents with abdominal symptoms, usually without evidence of shunt malfunction. The pathogenesis is likely related to perforation of bowel at the time of VP shunt placement or translocation of bacteria across the bowel wall. Thus, Gram-negative isolates predominate and mixed infection is common. The infecting organisms are often isolated from only the distal portion of the shunt.

Common pathogens responsible for community-acquired meningitis, including *S. pneumoniae*, *N. meningitidis*, and *H. influenzae* type b, can also cause bacterial meningitis in patients with shunts. The clinical presentation is similar to that for acute bacterial meningitis in other children (see Chapter 602.1).

**Treatment** of shunt colonization includes removal of the shunt and systemic antibiotic therapy directed against the isolated organisms. After collection of appropriate samples for culture, empiric therapy is usually with vancomycin plus an antipseudomonal agent with relatively good CSF penetration such as cefazidime or meropenem. Definitive therapy should be directed toward the isolate and account for poor penetration of most antibiotics into the CSF across noninflamed meninges. Accordingly, intraventricular antibiotics may be indicated but are usually reserved unless there is evidence of treatment failure. If the isolate is susceptible, a parenteral antistaphylococcal penicillin with or without intraventricular vancomycin is the treatment of choice. If the organism is resistant to penicillins, systemic vancomycin and possibly intraventricular vancomycin are recommended. In cases of Gram-negative infections, a combination of a third-generation cephalosporin with or without intraventricular aminoglycoside is optimal. When using intraventricular antibiotics, monitoring of CSF levels is necessary to avoid toxicity.

Removal of the colonized device is required for cure, and final replacement should be delayed until clearance of CSF cultures is documented. Many neurosurgeons immediately remove the shunt and place an external ventricular drain to relieve intracranial pressure, with a 2nd-stage shunt replacement once CSF sterilization has been confirmed. Others opt to initially exteriorize the distal end of the shunt, and replace the shunt in a single-stage procedure once CSF cultures remain sterile for 48-72 hr. Daily CSF cultures should be collected until clearance has been documented on 2-3 consecutive specimens, and antibiotics should be continued for at least 10 days after documented sterilization of the CSF. Gram-negative organisms may require a longer duration of therapy (up to 21 days). The CSF white cell count generally increases for the 1st 3-5 days of appropriate therapy and should not prompt concern for treatment failure. Distal shunt infection with peritonitis and wound infection are managed in a similar fashion.

**Treatment** of bacterial meningitis with typical community-acquired pathogens such as meningococcus or pneumococcus usually requires only systemic antibiotic therapy. Shunt replacement is not required in the absence of device malfunction, poor clinical response, persistent CSF culture positivity, or relapse of infection after antibiotic therapy.

**Prevention of Infection**

Prevention of shunt infection includes meticulous cutaneous preparation and surgical technique. Systemic and intraventricular antibiotics, antibiotic-impregnated shunts, and soaking the shunt tubing in antibiotics are used to reduce the incidence of infection, with varying success. Systemic prophylactic antibiotics given prior to shunt insertion reduce the risk for infection and should be used routinely. Antibiotic-impregnated catheters also appear to reduce the risk of infection, although limited evidence is available, and may be used in high-risk patients where the devices are available.

**URETHRAL CATHETERS**

Urinary catheters are a frequent cause of nosocomial infection, with about 14 infections per 1,000 admissions. Like other devices, microorganisms adhere to the catheter surface and establish a biofilm that allows proliferation. The physical presence of the catheter reduces the normal host defenses by preventing complete emptying of the bladder, thus providing a medium for growth, distending the urethra, and blocking periurethral glands. Almost all patients catheterized for longer than 30 days develop bacteriuria. The organism burden in catheter-associated urinary tract infection is typically ≥10,000 colony-forming units/mL. Lower thresholds may be used where there is a high index of suspicion, but these episodes may represent colonization rather than infection. Urine culture should only be performed in catheterized patients when infection is suspected, as asymptomatic colonization is ubiquitous and may lead to overtreatment and subsequent development of bacterial resistance. Gram-negative bacilli and *Enterococcus* spp. are the predominant organisms isolated in catheter-related urinary tract infection; coagulase-negative staphylococci are implicated in approximately 15% of cases. Symptomatic urinary tract infections should be treated with antibiotics and catheter removal. Catheter colonization with *Candida* spp. is common but rarely leads to invasive infection, and treatment does not have a long-term impact on colonization. Treatment for asymptomatic candiduria is therefore not recommended except in neonates, immunocompromised patients, and those with urinary tract obstruction.

**Prevention of Infection**

All urinary catheters introduce a risk for infection, and their casual use should be avoided. When they are in place, their duration of use should be minimized. Technologic advances have led to development of silver- or antibiotic-impregnated urinary catheters that are associated with lower rates of infection. Prophylactic antibiotics do not significantly reduce the infection rates for long-term catheters but clearly increase the risk for infection with antibiotic resistant organisms.

**PERITONEAL DIALYSIS CATHETERS**

During the 1st yr of peritoneal dialysis for end-stage renal disease, 65% of children will have 1 or more episodes of peritonitis. Bacterial entry comes from luminal or periluminal contamination of the catheter or by translocation across the intestinal wall. Hematogenous infection is rare. Infections can be localized at the exit site or associated with peritonitis, or both. Organisms responsible for peritonitis include coagulase-negative staphylococci (30-40%), *S. aureus* (10-20%), streptococci (10-15%), *E. coli* (5-10%), *Pseudomonas* spp. (5-10%), other Gram-negative bacteria (5-15%), *Enterococcus* spp. (3-6%), and fungi (2-10%). *S. aureus* is more common in localized exit-site or tunnel-tract infections (42%). Most infectious episodes are caused by a patient’s own flora, and carriers of *S. aureus* have increased rates of infection as compared with noncarriers.

The **clinical manifestations** of peritonitis may be subtle and include low-grade fever with mild abdominal pain or tenderness. Cloudy peritoneal dialysis fluid may be the first and predominant sign. With peritonitis, the peritoneal fluid cell count is usually >100 white blood cells/μL. When peritonitis is suspected, the effluent dialysate should be submitted for a cell count, Gram stain, and culture. The Gram stain is positive in up to 40% of cases of peritonitis.

Patients with cloudy fluid and clinical symptoms should receive empiric therapy, preferably guided by results of a Gram stain. If no organisms are visualized, vancomycin and either an aminoglycoside or
third or fourth generation cephalosporin with antipseudomonal activity should be given via the intraperitoneal route. Blood levels should be measured for glycopeptides and aminoglycosides. Patients without cloudy fluid and with minimal symptoms may have therapy withheld pending culture results. Once the cause is identified by culture, changes in the therapeutic regimen may be needed. Oral rifampin may be added for *S. aureus* infections. Fungal peritonitis should be treated with a combination of oral flucytosine and intraperitoneal or oral fluconazole. The duration of therapy is a minimum of 14 days, with longer treatment of 21–28 days for episodes of *S. aureus*, *Pseudomonas* spp., and resistant Gram-negative bacteria and of 28–42 days for fungi. Repeat episodes of peritonitis within 4 wk of previous therapy represent “apparently relapsing” peritonitis. If the patient responds to reinstitution of antimicrobial therapy, a course of up to 6 wk should be continued. In all cases, if the infection fails to clear following appropriate therapy or if a patient’s condition is deteriorating, the catheter should be removed. Exit-site and tunnel infections may occur independently of peritonitis or may precede it. Appropriate antibiotics should be administered on the basis of Gram stain and culture findings and are typically given systemically only unless peritonitis is also present. Some experts recommend that the peritoneal catheter be removed if *Pseudomonas* or fungal organisms are isolated.

**Prevention of Infection**

In addition to usual hygienic practices, regular application of mupirocin or gentamicin cream to the catheter exit site reduces exit-site infections and peritonitis. Some practitioners recommend against the use of gentamicin cream because of the risk of infection with gentamicin-resistant bacteria. Systemic antibiotic prophylaxis should be considered at the time of catheter insertion, if there is accidental contamination, and at the time of dental procedures. Antifungal prophylaxis can be considered during antibiotic therapy to prevent fungal infection.

**ORTHOPEDIC PROSTHESES**

Orthopedic prostheses are used infrequently in children. Infection most often follows introduction of microorganisms at surgery through airborne contamination or direct inoculation; via hematogenous spread; or via contiguous spread from an adjacent infection. Early postoperative infection occurs within 2–4 wk of surgery with typical manifestations that include fever, pain, and local symptoms of wound infection. Rapid assessment, including isolation of the infecting organism by joint aspiration or intraoperative culture, operative debridement, and antimicrobial treatment may allow salvage of the implant if the duration of symptoms is less than 1 mo, the prosthesis is stable, and the pathogen is susceptible to antibiotics. Chronic infection presents >1 mo after surgery and is often caused by organisms of low virulence that contaminated the implant at the time of surgery. Typical manifestations include pain and deterioration in function. Local symptoms such as erythema, swelling, or drainage may also occur. These infections respond poorly to antibiotic treatment and usually require removal of the implant using either a 1- or 2-stage procedure. Surgical debridement of the site with long-term suppressive antibiotic therapy may be considered, but eradication of infection is uncommon. Acute hematogenous infections are most often observed 2 yr or more after surgery. Retention of the prosthesis is sometimes attempted, but there are inadequate long-term data to determine the success rate. If salvage therapy is attempted, prompt debridement and appropriate antibiotic therapy are recommended. As with other long-term implanted devices, the most common organisms are about equally divided between coagulase-negative staphylococci and *S. aureus*. With prior antibiotic therapy, the prosthesis culture may be negative; in these situations, determining 16S ribosomal RNA typing may help identify the organism.

The use of systemic antibiotic prophylaxis, antibiotic-containing bone cement, and operating rooms fitted with laminar airflow all have been proposed as beneficial in reducing infection. To date, results from clinical studies are conflicting.

Bibliography

Antibacterial therapy in infants and children presents many challenges. A daunting problem is the paucity of pediatric data regarding pharmacokinetics and optimal dosages; as a consequence, pediatric recommendations are commonly extrapolated from studies in adults. A second challenge is the need for the clinician to consider important differences among various age groups with respect to the pathogenic species responsible for pediatric bacterial infections. Age-appropriate antibiotic dosing and toxicities must be considered, taking into account the developmental status and physiology of infants and children. Finally, the style of usage of antibiotics has some important differences compared with usage in adult patients. Specific antibiotic therapy is optimally driven by a microbiologic diagnosis, predicated on isolation of the pathogenic organism from a sterile body site, and supported by antimicrobial susceptibility testing. Given the inherent difficulties that can arise in collecting specimens from pediatric patients, and given the high risk of mortality and disability associated with serious bacterial infections in very young infants, much of pediatric infectious diseases practice is based on a clinical diagnosis with empirical use of antibacterial agents, administered before or even without eventual identification of the specific pathogen.

Several key considerations influence decisions about the appropriate empirical use of antibacterial agents in infants and children. It is important to know the age-appropriate differential diagnosis with respect to likely pathogens. This information affects the choice of antimicrobial agent and also the dose, dosing interval, and route of administration (oral vs parenteral). A complete history and physical examination, combined with appropriate laboratory and radiographic studies, are necessary to identify specific diagnoses, in turn affecting the choice, dosing, and degree of urgency of administration of antimicrobial agents. The vaccination history may reflect reduced risk for some invasive infections, but not necessarily elimination of risk. The risk of serious bacterial infection in pediatric practice is also affected by the child’s immunologic status, which may be compromised by immaturity (neonates), underlying disease, and associated treatments (see Chapter 178). Infections in immunocompromised children may result from bacteria that are not considered pathogenic in immunocompetent children. The presence of foreign bodies also increases the risk of bacterial infections (see Chapter 179). The likelihood of central nervous system (CNS) involvement must be considered in all pediatric patients with serious bacterial infections, because many of the more common bacteremic infections in childhood, including disease caused by Haemophilus influenzae type b, pneumococcus, Salmonella, and meningococcus, carry a significant risk for hematogenous spread to the CNS.

The patterns of antimicrobial resistance in the community and for the potential causative pathogen being empirically treated must also be considered. Resistance to penicillin and cephalosporins is commonplace among strains of Streptococcus pneumoniae, often necessitating the use of other classes of antibiotics. Similarly, the striking emergence of community-acquired methicillin-resistant Staphylococcus aureus (MRSA) infections has complicated antibiotic choices for
this pathogen. Furthermore, carbapenem-resistant Enterobacteriaceae are an increasing problem among hospitalized patients.

Antimicrobial resistance occurs through many modifications of the bacterial genome (Tables 180-1 and 180-2). Mechanisms include enzyme inactivation of the antibiotic, decreased cell membrane permeability to intracellularly active antibiotics, efflux of antibiotics out of the bacteria, protection or alteration of the antibiotic target site, excessive production of the target site, and bypassing the antimicrobial site of action.

Antimicrobial resistance has reached crisis proportions, driven by the emergence of new resistance mechanisms (such as carbapenemases) and by overuse of antibiotics, both in healthcare and in other venues, such as agriculture. This increase in antibiotic resistance has rendered some bacterial infections encountered in clinical practice virtually untreatable. Accordingly, there is an urgent need to develop new antimicrobials. In addition, it is important for practitioners to use antibiotics only as necessary, with the narrowest feasible antimicrobial spectrum, to thwart emergence of resistance. Advocacy for vaccines, particularly conjugate pneumococcal vaccine, can also decrease the selective pressure that excessive antimicrobial use exerts on resistance.

Effective antibiotic action requires achieving therapeutic levels of the drug at the site of infection. Although measuring the level of antibiotic at the site of infection is not always possible, one may measure the serum level and use this level as a surrogate marker for achievement of the desired effect at the tissue level. Various target serum levels are appropriate for different antibiotic agents and are assessed by the peak and trough serum levels, and the area under the therapeutic drug level curve (Fig. 180-1). These levels are, in turn, a reflection of the route of administration, drug absorption (IM, PO), volume of distribution, and drug elimination half-life, as well as of drug-drug interactions that might enhance or impede enzymatic inactivation of an antibiotic or result in antimicrobial synergism or antagonism (Fig. 180-2).

A, amikacin; AAC, aminoglycoside acetyltransferase; ANT, aminoglycoside nucleotidytranferase; APH, aminoglycoside phosphotransferase; E, Enterobacteriaceae; G, gentamicin; K, kanamycin; PR, Providencia-Proteus; PS, pseudomonads; SA, staphylococci; SR, streptococci; T, tobramycin.

### AGE- AND RISK-SPECIFIC USE OF ANTIBIOTICS IN CHILDREN

#### Neonates

The causative pathogens of neonatal infections are typically acquired around the time of delivery. Thus, empirical antibiotic selection must take into account the importance of these pathogens in neonates (see Chapter 109). Among the causes of neonatal sepsis in infants, group B streptococcus is the most common, although intrapartum antibiotic prophylaxis administered to women at increased risk for transmission of this pathogen to the infant has greatly decreased the incidence of this infection in neonates (see Chapter 184). Gram-negative enteric organisms acquired from the maternal birth canal, in particular Escherichia coli, are other common causes of neonatal sepsis. Although rare, Listeria monocytogenes is also an important pathogen, insofar as it is intrinsically resistant to cephaplorcin antibiotics, which are often used as empirical therapy for serious bacterial infections in young children. Salmonella species are also being increasingly recognized as important pathogens in infancy. All of these organisms can be associated with meningitis in the neonate; therefore, lumbar puncture should always be considered in the setting of bacteremic infections in this age group, and, if meningitis cannot be excluded, antibiotic management should include agents capable of crossing the blood–brain barrier.

#### Older Children

Antibiotic choices in toddlers and young children were once driven by the high risk of this age group to invasive disease caused by H. influenzae type b (see Chapter 194). With the advent of conjugate vaccines against H. influenzae type b, invasive disease has declined dramatically. However, outbreaks of invasive disease still occur, particularly in the setting of parental refusal of vaccines. It is, therefore, still important to utilize antimicrobials that are active against this pathogen in many clinical settings, particularly if meningitis is a consideration. Other particularly important pathogens to be considered in this age group include E. coli, S. pneumoniae, Neisseria meningitidis, and S. aureus. Antimicrobial resistance is commonly exhibited by S. pneumoniae and S. aureus. Strains of S. pneumoniae that are resistant to penicillin and cephalosporin antibiotics are frequently encountered in clinical practice. Similarly, MRSA is highly prevalent in many regions. Resistance of S. pneumoniae, as well as MRSA, is a result of mutations that confer alterations in penicillin-binding proteins, the molecular targets of penicillin and cephalosporin activity (see Table 180-1).

Depending on the specific clinical diagnosis, other pathogens that are commonly encountered among older children include Moraxella catarrhalis, nontypable strains of H. influenzae, and Mycoplasma pneumoniae, which cause upper respiratory tract infections and pneumonia; group A streptococcus, which causes pharyngitis, skin and soft-tissue infections, osteomyelitis, septic arthritis, and, rarely, bactereemia with toxic shock syndrome; Kingella kingae, which causes bone and joint infections; viridans streptococci and Enterococcus, which cause endocarditis; and Salmonella, which causes enteritis, bactereemia, osteomyelitis, and septic arthritis. This complexity underscores the
Infectious Diseases

Immunocompromised and Hospitalized Patients

It is important to consider the risks associated with immunocompromising conditions (malignancy, solid-organ, or hematopoietic stem cell transplantation) and the risks conferred by conditions leading to prolonged hospitalization (intensive care, trauma, burns). Serious viral infections, particularly with influenza, can also predispose to invasive bacterial infections, especially with *S. aureus*. Immunocompromised children are predisposed to develop a wide range of bacterial, viral, fungal, or parasitic infections. Prolonged hospitalization can lead to nosocomial infections, often associated with indwelling lines and catheters and commonly caused by Gram-negative enteric organisms. In addition to the usual bacterial pathogens, *Pseudomonas aeruginosa* and enteric organisms, including *E. coli*, *Klebsiella pneumoniae*, *Enterobacter*, and *Serratia*, are important considerations as opportunistic pathogens in these settings. Selection of appropriate antimicrobials is challenging because of the diverse causes and scope of antimicrobial resistance exhibited by these organisms. Many strains of enteric organisms have resistance because of extended spectrum β-lactamases (see Table 180-1). Class B metallo-β-lactamases that hydrolyze all β-lactam antibiotics except aztreonam are increasingly being described. A worrisome development is the increasing reports of carbapenemases in *Enterobacteriaceae*. Carbapenemase-producing *Enterobacteriaceae* are different from other multidrug-resistant microorganisms in that they are susceptible to few (if any) antibacterial agents. *P. aeruginosa* encodes proteins that function as efflux pumps to eliminate multiple classes of antimicrobials from the cytoplasm or periplasmic space. In addition to these Gram-negative pathogens, infections caused by *Enterococcus faecalis* and *Enterococcus faecium* are inherently difficult to treat. These organisms may cause urinary tract infection or infective endocarditis in immunocompetent children and may be responsible for a variety of syndromes in immunocompromised patients, especially in the setting of prolonged intensive care. The emergence of infections caused by *vancomycin-resistant Enterococcus* (VRE) has further complicated antimicrobial selection in high-risk patients and has necessitated the development of newer antimicrobials that target these highly resistant Gram-positive bacteria. Although experience with many of these newer agents in the management of complex hospitalized pediatric patients is limited, they are important agents to be aware of (described below).

Infections Associated with Medical Devices

A special situation affecting antibiotic use is the presence of an indwelling medical device, such as a venous catheter, ventriculoperitoneal shunt, stent, or other catheter (see Chapter 179). In addition to *S. aureus*, coagulase-negative staphylococci are also a major...
Consideration. Coagulase-negative staphylococci seldom cause serious
disease without a risk factor such as an indwelling catheter. Empirical
antibiotic regimens must take this risk into consideration. In addition
to appropriate antibiotic therapy, removal or replacement of the colo-
nized prosthetic material is commonly required for cure.

**ANTIBIOTICS COMMONLY USED IN PEDIATRIC PRACTICE**

Table 180-3 lists commonly used antibiotics.

**Penicillins**

Although there has been ever-increasing emergence of resistance to
penicillins, these agents remain valuable and are commonly used for
management of many pediatric infectious diseases.

Penicillins remain the drugs of choice for pediatric infections
caused by group A and group B Streptococcus, Treponema pallidum
(syphilis), *L. monocytogenes*, and *N. meningitidis*. The semisynthetic
penicillins (nafcillin, cloxacillin, dicloxacillin) are useful for manage-
fment of susceptible staphylococcal infections, although the increasing
incidence of MRSA has limited the usefulness of these drugs. The
aminopenicillins (ampicillin, amoxicillin) were developed to provide
broad-spectrum activity against Gram-negative organisms, including
*E. coli* and *H. influenzae*, but the emergence of resistance has limited
their utility in many clinical settings. The carboxypenicillins (carbeni-
cillin, ticarcillin) and uredopenicillins (piperacillin, ticlopidin, azlocillin)
also have bactericidal activity against most strains of
*P. aeruginosa.*

---

**Table 180-3** Antibacterial Medications (Antibiotics)*

<table>
<thead>
<tr>
<th>DRUG (TRADE NAMES, FORMULATIONS)</th>
<th>INDICATIONS (MECHANISM OF ACTION) AND DOSING</th>
<th>COMMENTS</th>

<tbody>
<tr>
<td>Amikacin sulfate Amikin Injection: 50 mg/mL, 250 mg/mL</td>
<td>Aminoglycoside antibiotic active against Gram-negative bacilli, especially <em>Escherichia coli</em>, <em>Klebsiella</em>, <em>Proteus</em>, <em>Enterobacter</em>, <em>Serratia</em>, and <em>Pseudomonas</em> Neonates: Postnatal age ≤7 days: weight 1,200-2,000 g: 7.5 mg/kg q 12-18 hr IV or IM; weight &gt;2,000 g: 10 mg/kg q 12 hr IV or IM; postnatal age &gt;7 days: weight 1,200-2,000 g IV or IM: 7.5 mg/kg q 8-12 hr IV or IM; weight &gt;2,000 g: 10 mg/kg q 8 hr IV or IM Children: 15-25 mg/kg/24 hr divided q 8-12 hr IV or IM Adults: 15 mg/kg/24 hr divided q 8-12 hr IV or IM</td>
<td>Cautions: Anaerobes, Streptococcus (including <em>S. pneumoniae</em>) are resistant. May cause ototoxicity and nephrotoxicity. Monitor renal function. Drug eliminated renally. Administered IV over 30-60 min Drug interactions: May potentiate other ototoxic and nephrotoxic drugs Target serum concentrations: Peak 25-40 mg/L; trough &lt;10 mg/L</td>
</tr>
<tr>
<td>Amoxicillin Amoxil, Polymox Capsule: 250, 500 mg Tablet: chewable: 125, 250 mg Suspension: 125 mg/5 mL, 250 mg/5 mL Drops: 50 mg/mL</td>
<td>Penicillinase-susceptible β-lactam: Gram-positive pathogens except <em>Staphylococcus</em>, <em>Salmonella</em>, <em>Shigella</em>, <em>Neisseria</em>, <em>E. coli</em>, and <em>Proteus mirabilis</em> Children: 20-50 mg/kg/24 hr divided q 8-12 hr PO. Higher dose of 80-90 mg/kg/24 hr PO for otitis media Adults: 250-500 mg q 8-12 hr PO Uncomplicated gonorrhea: 3 g with 1 g probenecid PO</td>
<td>Cautions: Rash, diarrhea, abdominal cramping. Drug eliminated renally Drug interaction: Probenecid</td>
</tr>
<tr>
<td>Amoxicillin-clavulanate Augmentin Tablet: 250, 500, 875 mg Table: chewable: 125, 200, 250, 400 mg Suspension: 125 mg/5 mL, 200 mg/5 mL, 250 mg/5 mL, 400 mg/5 mL</td>
<td>β-Lactam (amoxicillin) combined with β-lactamase inhibitor (clavulanate) enhances amoxicillin activity against penicillinase-producing bacteria. <em>S. aureus</em> (not methicillin-resistant organism), <em>Streptococcus</em>, <em>Haemophilus influenzae</em>, <em>Moraxella catarrhalis</em>, <em>E. coli</em>, <em>Klebsiella</em>, <em>Bacteroides fragilis</em> Neonates: 30 mg/kg/24 hr divided q 12 hr PO Children: 20-45 mg/kg/24 hr divided q 8-12 hr PO. Higher dose 80-90 mg/kg/24 hr PO for otitis media Adults: 20-45 mg/kg/24 hr divided q 8-12 hr PO. Higher dose 80-90 mg/kg/24 hr PO for otitis media</td>
<td>Cautions: Drug dosed on amoxicillin component. May cause diarrhea, rash. Drug eliminated renally Drug interaction: Probenecid Comment: Higher dose may be active against penicillin-tolerant/resistant <em>S. pneumoniae</em></td>
</tr>
<tr>
<td>Ampicillin Polyclin, Omniben Capsule: 250, 500 mg Injection: 125 mg/5 mL, 250 mg/5 mL, 500 mg/5 mL</td>
<td>β-Lactam with same spectrum of antibacterial activity as amoxicillin Neonates: Postnatal age ≤7 days weight ≤2,000 g: 50 mg/kg/24 hr IV or IM q 12 hr (meningitis: 100 mg/kg/24 hr divided q 12 hr IV or IM); weight &gt;2,000 g: 75 mg/kg/24 hr divided q 8 hr IV or IM (meningitis: 150 mg/kg/24 hr divided q 8 hr IV or IM). Postnatal age &gt;7 days weight &lt;1,200 g: 50 mg/kg/24 hr IV or IM q 12 hr (meningitis: 100 mg/kg/24 hr divided q 12 hr IV or IM); weight 1,200-2,000 g: 75 mg/kg/24 hr divided q 8 hr IV or IM (meningitis: 150 mg/kg/24 hr divided q 8 hr IV or IM); weight &gt;2,000 g: 100 mg/kg/24 hr divided q 6 hr IV or IM (meningitis: 200 mg/kg/24 hr divided q 6 hr IV or IM) Children: 100-200 mg/kg/24 hr divided q 6 hr IV or IM (meningitis: 200-400 mg/kg/24 hr divided q 4-6 hr IV or IM) Adults: 250-500 mg q 4-8 hr IV or IM</td>
<td>Cautions: Less bioavailable than amoxicillin, causing greater diarrhea Drug interaction: Probenecid</td>
</tr>
<tr>
<td>Amoxicillin-sulbactam Unasyn Injection</td>
<td>β-Lactam (ampicillin) and β-lactamase inhibitor (sulbactam) enhances ampicillin activity against penicillinase-producing bacteria: <em>S. aureus</em>, <em>H. influenzae</em>, <em>M. catarrhalis</em>, <em>E. coli</em>, <em>Klebsiella</em>, <em>B. fragilis</em> Children: 100-200 mg/kg/24 hr divided q 4-8 hr IV or IM Adults: 1-2 g q 6-8 hr IV or IM (max daily dose: 8 g)</td>
<td>Cautions: Drug dosed on ampicillin component. May cause diarrhea, rash. Drug eliminated renally Note: Higher dose may be active against penicillin-tolerant/resistant <em>S. pneumoniae</em> Drug interaction: Probenecid</td>
</tr>

### Antibacterial Medications (Antibiotics)—cont’d

<table>
<thead>
<tr>
<th>Drug (Trade Names, Formulations)</th>
<th>Indications (Mechanism of Action) and Dosing</th>
<th>Comments</th>
</tr>
</thead>
</table>

**Cefixime**
Suprax
Tablet: 200, 400 mg
Suspension: 100 mg/5 mL

Third-generation cephalosporin active against *streptococci, H. influenzae, M. catarrhalis, Neisseria gonorrhoeae, Serratia marcescens*, and *Proteus vulgaris*. No antistaphylococcal or antipseudomonal activity

- Children: 8 mg/kg/24 hr divided q 12-24 hr PO
- Adults: 400 mg/24 hr divided q 12-24 hr PO

Cautions: β-Lactam safety profile (rash, eosinophilia). Renally eliminated. Does not adequately penetrate CNS

**Drug interaction:** Probenecid

**Cefoperazone sodium**
Cefobid
Intramuscular injection

Third-generation cephalosporin active against many Gram-positive and Gram-negative pathogens

- Neonates: 100 mg/kg/24 hr divided q 12 hr IV or IM; >7 days: weight <1,200 g: 150 mg/kg/24 hr divided q 8 hr IV or IM; >1,200 g: 200 mg/kg/24 hr divided q 8 hr IV or IM
- Children: 150 mg/kg/24 hr divided q 6-8 hr IV or IM (meningitis: 200 mg/kg/24 hr divided q 6-8 hr IV)
- Adults: 1-2 g q 12-24 hr IV or IM (max dose: 12 g/24 hr)

Cautions: Highly protein-bound cephalosporin with limited potency reflected by weak antipseudomonal activity. Primarily hepatically eliminated in bile

**Drug interaction:** Disulfiram-like reaction with alcohol

**Cefotetan disodium**
Cefotan
Injection

Second-generation cephalosporin active against *S. aureus, Streptococcus, H. influenzae, E. coli, Klebsiella, Proteus, and Bacteroides*. Inactive against *Enterobacter*

- Children: 40-80 mg/kg/24 hr divided IV or IM q 12 hr
- Adults: 2-4 g/24 hr divided q 12 hr IV or IM (max dose: 6 g/24 hr)

Cautions: Poor CNS penetration; β-lactam safety profile (rash, eosinophilia). Renally eliminated. Painful given intramuscularly

**Drug interaction:** Probenecid

**Cefoxitin sodium**
Mefoxin
Injection

Second-generation cephalosporin active against *S. aureus, Streptococcus, H. influenzae, E. coli, Klebsiella, Proteus, and Bacteroides*. Inactive against *Enterobacter*

- Neonates: 70-100 mg/kg/24 hr divided q 8-12 hr IV or IM
- Children: 80-160 mg/kg/24 hr divided q 8-12 hr IV or IM
- Adults: 1-2 g q 6-8 hr IV or IM (max dose: 12 g/24 hr)

Cautions: Poor CNS penetration; β-lactam safety profile (rash, eosinophilia). Renally eliminated. Painful given intramuscularly

**Drug interaction:** Probenecid

**Cefpodoxime proxetil**
Vantin
Tablet: 100 mg, 200 mg
Suspension: 50 mg/5 mL, 100 mg/5 mL

Third-generation cephalosporin active against *S. aureus, Streptococcus, H. influenzae, M. catarrhalis, N. gonorrhoeae, E. coli, Klebsiella, and Proteus*. No antipseudomonal activity

- Children: 10 mg/kg/24 hr divided q 12 hr PO
- Adults: 200-800 mg/24 hr divided q 12 hr PO (max dose: 800 mg/24 hr)

Cautions: β-Lactam safety profile (rash, eosinophilia). Renally eliminated. Does not adequately penetrate CNS. Increased bioavailability when taken with food

**Drug interaction:** Probenecid; antacids and H2 receptor antagonists may decrease absorption

**Ceftaroline fosamil**
Teflaro
Injection

Fifth-generation cephalosporin active against *S. aureus* (including MRSA when used for skin and soft-tissue infection), *Streptococcus pyogenes*, *Streptococcus agalactiae*, *Escherichia coli*, *Klebsiella pneumoniae*, *H. influenzae*, and *Klebsiella oxytoca*

- Children: 4 mg/kg/24 hr divided q 8 hr IV (<6 mo of age); 36 mg/kg/24 hr divided q 8 hr IV (weight ≤33 kg); 400 mg q 8 hr IV (weight >33 kg)
- Adults: 600 mg q 12 hr IV

*Children: 24 mg/kg/24 hr divided q 8 hr IV (≤6 mo of age); 36 mg/kg/24 hr divided q 8 hr IV (weight ≤33 kg); 400 mg q 8 hr IV (weight >33 kg)

*Adolts: 600 mg q 12 hr IV

*Suggested dose; safety and effectiveness in pediatric patients have not yet been established

Cautions: β-Lactam safety profile (rash, eosinophilia). Renally eliminated. Good bioavailability; food does not affect bioavailability

**Drug interaction:** Probenecid

*In the Drug column, the generic drug name is in bold. In the Indications column, bold indicates major organisms targeted and mechanisms of action.*

<tr>
<td><strong>Ciprofloxacin</strong>&lt;br&gt;Cipro&lt;br&gt;Tablet: 100, 250, 500, 750 mg&lt;br&gt;Injection&lt;br&gt;Ophthalmic solution and ointment&lt;br&gt;Otic suspension&lt;br&gt;Oral suspension: 250 and 500 mg/5 mL</td>
<td>Quinolone antibiotic active against <em>P. aeruginosa</em>, <em>Serratia</em>, <em>Enterobacter</em>, <em>Shigella</em>, <em>Salmonella</em>, <em>Campylobacter</em>, <em>N. gonorrhoeae</em>, <em>H. influenzae</em>, <em>M. catarrhalis</em>, some <em>S. aureus</em>, and some <em>Streptococcus</em>&lt;br&gt;Neonates: 10 mg/kg q 12 hr PO or IV&lt;br&gt;Children: 15-30 mg/kg/24 hr divided q 12 hr PO or IV; cystic fibrosis: 20-40 mg/kg/24 hr divided q 8-12 hr PO or IV&lt;br&gt;Adults: 250-750 mg q 12 hr; 200-400 mg IV q 12 hr PO (max dose: 1.5 g/24 hr)</td>
<td>Cautions: Concerns of joint destruction in juvenile animals not seen in humans; tendonitis, superinfection, dizziness, confusion, crystalluria, some photosensitivity&lt;br&gt;Drug interactions: Theophylline; magnesium-, aluminum-, or calcium-containing antacids; sucralfate; probenecid; warfarin; cyclosporine</td>
</tr>
<tr>
<td><strong>Clarithromycin</strong>&lt;br&gt;Biaxin&lt;br&gt;Tablet: 250, 500 mg&lt;br&gt;Suspension: 125 mg/5 mL, 250 mg/5 mL</td>
<td>Macrolide antibiotic with activity against <em>S. aureus</em>, <em>Streptococcus</em>, <em>H. influenzae</em>, <em>Legionella</em>, <em>Mycoplasma</em>, and <em>C. trachomatis</em>&lt;br&gt;Children: 15 mg/kg/24 hr divided q 12 hr PO&lt;br&gt;Adults: 250-500 mg q 12 hr PO (max dose: 1 g/24 hr)</td>
<td>Cautions: Adverse events less than erythromycin; gastrointestinal upset; dyspepsia, nausea, cramping&lt;br&gt;Drug interactions: Same as erythromycin: astemizole, carbamazepine, terfenadine, cyclosporine, theophylline, digoxin, tacrolimus</td>
</tr>
<tr>
<td><strong>Clindamycin</strong>&lt;br&gt;Cleocin&lt;br&gt;Capsule: 75, 150, 300 mg&lt;br&gt;Injection&lt;br&gt;Topical solution, lotion, and gel&lt;br&gt;Vaginal cream</td>
<td>Protein synthesis inhibitor active against most Gram-positive aerobic and anaerobic cocci except <em>Enterococcus</em>&lt;br&gt;Neonates: Postnatal age ≤7 days weight &lt;2,000 g: 10 mg/kg/24 hr divided q 12 hr IV or IM; weight &gt;2,000 g: 15 mg/kg/24 hr divided q 8 hr IV or IM; &gt;7 days weight &lt;1,200 g: 10 mg/kg/24 hr IV or IM divided q 12 hr; weight 1,200-2,000 g: 15 mg/kg/24 hr divided q 8 hr IV or IM; weight &gt;2,000 g: 20 mg/kg/24 hr divided q 8 hr IV or IM&lt;br&gt;Children: 10-40 mg/kg/24 hr divided q 6-8 hr IV, IM, or PO&lt;br&gt;Adults: 150-600 mg q 6-8 hr IV, IM, or PO (max dose: 5 g/24 hr IV or IM or 2 g/24 hr PO)</td>
<td>Cautions: Diarrhea, nausea, Clostridium difficile-associated colitis, rash&lt;br&gt;Admister slow IV over 30-60 min Topically active as an acne treatment</td>
</tr>
<tr>
<td><strong>Cloxacillin sodium</strong>&lt;br&gt;Tegopen&lt;br&gt;Capsule: 250, 500 mg&lt;br&gt;Suspension: 125 mg/5 mL</td>
<td>Penicillinase-resistant penicillin active against <em>S. aureus</em> and other Gram-positive cocci except <em>Enterococcus</em> and coagulase-negative staphylococci&lt;br&gt;Children: 50-100 mg/kg/24 hr divided q 6 hr PO&lt;br&gt;Adults: 250-500 mg q 6 hr PO (max dose: 4 g/24 hr)</td>
<td>Cautions: β-Lactam safety profile (rash, eosinophilia). Primarily heptatically eliminated; requires dose reduction in renal disease. Food decreases bioavailability&lt;br&gt;Drug interaction: Probenecid</td>
</tr>
<tr>
<td><strong>Colistin (Colistimethate sodium; polymyxin E)</strong>&lt;br&gt;Injection&lt;br&gt;Inhalation</td>
<td>Treatment of multidrug resistant Gram-negative organisms (Enterobacteriaceae including extended-spectrum betalactamase and carbapenemase-producing strains)&lt;br&gt;Children: 2.5-5 mg/kg/day divided in 2-4 divided doses IV&lt;br&gt;Adults: 300 mg/day in 2-4 divided doses IV</td>
<td>Cautions: Nephrotoxicity (~3% in young children; higher rates in adolescents and adults); adjust dose for renal insufficiency; neurotoxicity (headaches, paresthesia, ataxia)&lt;br&gt;Drug interactions: Should not be administered concomitantly with polymyxins or aminoglycosides</td>
</tr>
<tr>
<td><strong>Co-trimoxazole (trimethoprim-sulfamethoxazole; TMP-SMZ)</strong>&lt;br&gt;Bactrim, Cotrim, Septra, Sulfatrim&lt;br&gt;Tablet: SMZ 400 mg and TMP 80 mg&lt;br&gt;Tablet DS: SMZ 800 mg and TMP 160 mg&lt;br&gt;Suspension: SMZ 200 mg and TMP 40 mg/5 mL&lt;br&gt;Injection</td>
<td>Antibiotic combination with sequential antagonism of bacterial folate synthesis with broad antibacterial activity: <em>Shigella</em>, <em>Legionella</em>, <em>Nocardia</em>, <em>Chlamydia</em>, <em>Pneumocystis jiroveci</em>. Dosage based on TMP component&lt;br&gt;Children: 6-20 mg TMP/kg/24 hr or IV divided q 12 hr PO&lt;br&gt;<em>Pneumocystis carinii</em> pneumonia: 15-20 mg TMP/kg/24 hr divided q 12 hr PO or IV&lt;br&gt;<em>P. carinii</em> prophylaxis: 5 mg TMP/kg/24 hr or 3 times/wk PO&lt;br&gt;Adults: 160 mg TMP q 12 hr PO</td>
<td>Cautions: Drug dosed on TMP (trimethoprim) component. Sulfonamide skin reactions: rash, erythema multiforme, Stevens-Johnson syndrome, nausea, leukopenia. Renal and hepatic elimination; reduce dose in renal failure&lt;br&gt;Drug interactions: Protein displacement with warfarin, possibly phenytoin, cyclosporine</td>
</tr>

<table>
<thead>
<tr>
<th>DRUG (TRADE NAMES, FORMULATIONS)</th>
<th>INDICATIONS (MECHANISM OF ACTION)</th>
<th>DOSING</th>
<th>COMMENTS</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Daptomycin</strong>&lt;br&gt;Cubicin</td>
<td>Disrupts bacterial cell membrane function, causing depolarization leading to inhibition of protein, DNA and RNA synthesis, which results in bacterial cell death. Active against enterococci (including glycopeptide-resistant strains), staphylococci (including MRSA), streptococci, and corynebacteria. Approved for skin and soft-tissue infections. Acceptable for bacteremia and right-sided endocarditis with susceptible strains&lt;br&gt;Adults: In skin and soft-tissue infections, 4 mg/kg daptomycin is given intravenously once daily. For S. aureus bacteremia or right-sided endocarditis, the approved dose is 6 mg/kg given intravenously once daily&lt;br&gt;Children: Unknown. Doses of 5-9 mg/kg/day in once-daily dosing have been reported in pediatric clinical trials</td>
<td></td>
<td>Cautions: Should not be used for pneumonia as drug inactivated by surfactants. Associated with rash, renal failure, anemia, headache. Is reported to cause myopathy, rhabdomyolysis, and eosinophilic pneumonia&lt;br&gt;Drug interactions: Should not be administered with statins</td>
</tr>
<tr>
<td><strong>Demeclocycline</strong>&lt;br&gt;Declomycin&lt;br&gt;Tablet: 150, 300 mg&lt;br&gt;Capsule: 150 mg</td>
<td>Tetracycline active against most Gram-positive cocci except Enterococcus, many Gram-negative bacilli, anaerobes, <em>Borrelia burgdorferi</em> (Lyme disease), <em>Mycoplasma</em>, and <em>Chlamydia</em>&lt;br&gt;Adults: 100-200 mg/24 hr divided q 12-24 hr PO&lt;br&gt;Children: dose unknown. Adults: 500 mg q 8 hr IV</td>
<td></td>
<td>Cautions: Teeth staining, possibly permanent (if administered &lt;8 yr of age) with prolonged use; photosensitivity, diabetes insipidus, nausea, vomiting, diarrhea, superinfections&lt;br&gt;Drug interactions: Aluminum-, calcium-, magnesium-, zinc- and iron-containing food, milk, dairy products may decrease absorption</td>
</tr>
<tr>
<td><strong>Dicloxacillin</strong>&lt;br&gt;Doribax&lt;br&gt;Injection</td>
<td>Carbapenem antibiotic with broad-spectrum activity against Gram-positive cocci and Gram-negative bacilli, including <em>P. aeruginosa</em> and anaerobes&lt;br&gt;Children: dose unknown. Adults: 500 mg q 8 hr IV</td>
<td></td>
<td>Cautions: β-Lactam safety profile; does not undergo hepatic metabolism. Renal elimination (70-75%); dose adjustment for renal failure&lt;br&gt;Drug interactions: Valproic acid, probenecid</td>
</tr>
<tr>
<td><strong>Doxycline</strong>&lt;br&gt;Vibramycin, Doxy&lt;br&gt;Injection&lt;br&gt;Capsule: 50, 100 mg&lt;br&gt;Tablet: 50, 100 mg&lt;br&gt;Suspension: 25 mg/5 mL&lt;br&gt;Syrup: 50 mg/5 mL</td>
<td>Tetracycline antibiotic active against most Gram-positive cocci except Enterococcus, many Gram-negative bacilli, anaerobes, <em>B. burgdorferi</em> (Lyme disease), <em>Mycoplasma</em>, and <em>Chlamydia</em>&lt;br&gt;Children: 2-5 mg/kg/24 hr divided q 12-24 hr PO or IV (max dose: 200 mg/24 hr)&lt;br&gt;Adults: 100-200 mg/24 hr divided q 12-24 hr PO or IV</td>
<td></td>
<td>Cautions: Teeth staining, possibly permanent (&lt;8 yr of age) with prolonged use; photosensitivity, nausea, vomiting, diarrhea, superinfections&lt;br&gt;Drug interactions: Aluminum-, calcium-, magnesium-, zinc-, iron-, kaolin-, and pectin-containing products, food, milk, dairy products may decrease absorption. Carbamazepine, rifampin, barbiturates may decrease half-life</td>
</tr>
<tr>
<td><strong>Erythromycin</strong>&lt;br&gt;E-Mycin, Ery-Tab, Ery, Ilosone&lt;br&gt;Estolate 125, 500 mg&lt;br&gt;Tablet EES: 200 mg&lt;br&gt;Tablet base: 250, 333, 500 mg&lt;br&gt;Suspension: estolate 125 mg/5 mL, 250 mg/5 mL, EES 200 mg/5 mL, 400 mg/5 mL&lt;br&gt;Estolate drops: 100 mg/mL&lt;br&gt;EES drops: 100 mg/2.5 mL&lt;br&gt;Available in combination with sulfisoxazole (Pedialyte), dosed on erythromycin content</td>
<td>Bacteriostatic macrolide antibiotic most active against Gram-positive organisms, <em>Corynebacterium diphtheriae</em>, and <em>Mycoplasma pneumoniae</em>&lt;br&gt;Neonates: Postnatal age ≤7 days: 20 mg/kg/24 hr divided q 12 hr PO; ≥7 days weight ≤1,000 g: 20 mg/kg/24 hr divided q 12 hr PO; weight &gt;1,000 g: 30 mg/kg/24 hr divided q 8 hr PO (give as 5 mg/kg/dose q 6 hr to improve feeding intolerance)&lt;br&gt;Children: Usual max dose 2 g/24 hr&lt;br&gt;Base: 30-50 mg/kg/24 hr divided q 6-8 hr PO&lt;br&gt;Estolate: 30-50 mg/kg/24 hr divided q 8-12 hr PO&lt;br&gt;Stearate: 20-40 mg/kg/24 hr divided q 6 hr PO&lt;br&gt;Lactobionate: 20-40 mg/kg/24 hr divided q 6-8 hr IV&lt;br&gt;Gluceptate: 20-50 mg/kg/24 hr divided q 6 hr IV; usual max dose 4 g/24 hr IV&lt;br&gt;Adults: Base: 333 mg PO q 8 hr; estolate/stearate/base: 250-500 mg q 6 hr PO</td>
<td></td>
<td>Cautions: Motilin agonist leading to marked abdominal cramping, nausea, vomiting, diarrhea. Associated with hypertrophic pyloric stenosis in young infants. Many different salts with questionable tempering of gastrointestinal adverse events. Rare cardiac toxicity with IV use. Dose of salts differ. Topical formulation for treatment of acne&lt;br&gt;Drug interactions: Antagonizes hepatic CYP 3A4 activity: astemizole, carbamazepine, verapamil, cyclosporine, theophylline, digoxin, tacrolimus, carbamazepine</td>
</tr>

<th>DRUG (TRADE NAMES, FORMULATIONS)</th>
<th>INDICATIONS (MECHANISM OF ACTION) AND DOsing</th>
<th>COMMENTS</th>
</tr>
</thead>
<tbody>
<tr>
<td>Gentamicin Garamycin Injection Ophthalmic solution, ointment, topical cream</td>
<td>Aminoglycoside antibiotic active against Gram-negative bacilli, especially <em>E. coli</em>, <em>Klebsiella</em>, <em>Proteus</em>, <em>Enterobacter</em>, <em>Serratia</em>, and <em>Pseudomonas</em> Neonates: Postnatal age ≤7 days weight 1,200-2,000 g: 2.5 mg/kg q 12-18 hr IV or IM; weight &lt;2,000 g: 2.5 mg/kg q 12 hr IV or IM; postnatal age &gt;7 days weight 1,200-2,000 g: 2.5 mg/kg q 8-12 hr IV or IM; weight &gt;2,000 g: 2.5 mg/kg q 8 hr IV or IM Children: 2.5 mg/kg/24 hr divided q 8-12 hr IV or IM Alternatively may administer 5-7.5 mg/kg/24 hr IV once daily Intrathecal: Preservative-free preparation for intraventricular or intrathecal use: neonate: 1 mg/24 hr; children: 1-2 mg/24 hr intrathecal; adults: 4-8 mg/24 hr Adults: 3-6 mg/kg/24 hr divided q 8 hr IV or IM</td>
<td>Cautions: Anaerobes, <em>S. pneumoniae</em>, and other <em>Streptococcus</em> are resistant. May cause ototoxicity and nephrotoxicity. Monitor renal function. Drug eliminated renally. Administered IV over 30-60 min Drug interactions: May potentiate other ototoxic and nephrotoxic drugs Target serum concentrations: Peak 6-12 mg/L; trough &gt;2 mg/L with intermittent daily dose regimens only</td>
</tr>
<tr>
<td>Imipenem-cilastatin Primaxin Injection</td>
<td>Carbapenem antibiotic with broad-spectrum activity against Gram-positive cocci and Gram-negative bacilli, including <em>P. aeruginosa</em> and anaerobes. No activity against <em>Stenotrophomonas maltophilia</em> Neonates: Postnatal age ≤7 days weight &lt;1,200 g: 20 mg/kg q 18-24 hr IV or IM; weight &gt;1,200 g: 40 mg/kg divided q 12 hr IV or IM; postnatal age &gt;7 days weight 1,200-2,000 g: 40 mg/kg q 12 hr IV or IM; weight &gt;2,000 g: 60 mg/kg q 8 hr IV or IM Children: 60-100 mg/kg/24 hr divided q 6-8 hr IV or IM Adults: 2-4 g/24 hr divided q 6-8 hr IV or IM (max dose: 4 g/24 hr)</td>
<td>Cautions: β-Lactam safety profile (rash, eosinophilia), nausea, seizures. Cilastatin possesses no antibacterial activity; reduces renal imipenem metabolism. Primarily renally eliminated Drug interaction: Possibly ganciclovir</td>
</tr>
<tr>
<td>Linezolid Zyvox Tablet: 400, 600 mg Oral suspension: 100 mg/5 mL Injection: 100 mg/5 mL</td>
<td>Oxazolidinone antibiotic active against Gram-positive cocci (especially drug-resistant organisms), including <em>Staphylococcus</em>, <em>Streptococcus</em>, <em>E. faecium</em>, and <em>Enterococcus faecalis</em>. Interferes with protein synthesis by binding to 50S ribosome subunit Adults: Pneumonia: 600 mg q 12 hr IV or PO; skin infections: 400 mg q 12 hr IV or PO</td>
<td>Adverse events: Myelosuppression, pseudomembranous colitis, nausea, diarrhea, headache Drug interaction: Probencid</td>
</tr>
<tr>
<td>Lorabid Loracarbeff Lorabid Capsule: 200 mg Suspension: 100 mg/5 mL, 200 mg/5 mL</td>
<td>Carbacephem very closely related to cefaclor (second-generation cephalosporin) active against <em>S. aureus</em>, <em>Streptococcus</em>, <em>H. influenzae</em>, <em>M. catarrhalis</em>, <em>E. coli</em>, <em>Klebsiella</em>, and <em>Proteus</em> Children: 30 mg/kg/24 hr divided q 12 hr PO (max dose: 2 g) Adults: 200-400 mg q 12 hr PO (max dose: 800 mg/24 hr)</td>
<td>Cautions: β-Lactam safety profile (rash, eosinophilia). Renally eliminated Drug interaction: Probencid</td>
</tr>
<tr>
<td>Meropenem Merrem Injection</td>
<td>Carbapenem antibiotic with broad-spectrum activity against Gram-positive cocci and Gram-negative bacilli, including <em>P. aeruginosa</em> and anaerobes. No activity against <em>S. maltophilia</em> Children: 60 mg/kg/24 hr divided q 8 hr IV meningitis: 120 mg/kg/24 hr (max dose: 6 g/24 hr) q 8 hr IV Adults: 1.5-3 g q 8 hr IV</td>
<td>Cautions: β-Lactam safety profile; appears to possess less CNS excitation than imipenem. 80% renal elimination Drug interaction: Probencid</td>
</tr>
<tr>
<td>Metronidazole Flagyl, Metro I.V. Topical gel, vaginal gel Injection Tablet: 250, 500 mg</td>
<td>Highly effective in the treatment of infections caused by anaerobes. Oral therapy of <em>C. difficile</em> colitis Neonates: weight &lt;1,200 g: 7.5 mg/kg 48 hr PO or IV; postnatal age ≤7 days weight 1,200-2,000 g: 7.5 mg/kg/24 hr q 24 hr PO or IV; weight 2,000 g: 15 mg/kg/24 hr divided q 12 hr PO or IV; postnatal age &gt;7 days weight 1,200-2,000 g: 15 mg/kg/24 hr divided q 12 hr PO or IV; weight &gt;2,000 g: 30 mg/kg/24 hr divided q 12 hr PO or IV Children: 30 mg/kg/24 hr divided q 6-8 hr PO or IV Adults: 30 mg/kg/24 hr divided q 6 hr PO or IV (max dose: 4 g/24 hr)</td>
<td>Cautions: Dizziness, seizures, metallic taste, nausea, disulfiram-like reaction with alcohol. Administer IV slow over 30-60 min. Adjust dose with hepatic impairment Drug interactions: Carbamazepine, rifampin, phenobarbital may enhance metabolism; may increase levels of warfarin, phenytoin, lithium</td>
</tr>

</table>
| **Piperacillin-tazobactam**  
Zosyn, Injection | Extended-spectrum penicillin (piperacillin) combined with a β-lactamase inhibitor (tazobactam) active against *S. aureus*, *H. influenzae*, *E. coli*, *Enterobacter*, *Serratia*, *Acinetobacter*, *P. aeruginosa*, and *Bacteroides*  
Children: 300-400 mg/kg/24 hr divided q 6-8 hr IV or IM  
Adults: 3.375 g q 6-8 hr IV or IM | Cautions: β-Lactam safety profile (rash, eosinophilia); painful given intramuscularly; each gram contains 1.9 mEq sodium  
Interferes with platelet aggregation, serum sickness–like reaction with high doses, increases in liver function test results. Renally eliminated  
Drug interaction: Probencid |
| **Quinupristin/dalfopristin**  
Synercid, IV injection: powder for reconstitution, 10 mL contains 150 mg quinupristin, 350 mg dalfopristin | Streptogramin antibiotic (quinupristin) active against vancomycin-resistant *E. faecium* (VRE) and methicillin-resistant *S. aureus* (MRSA). Not active against *E. faecalis*  
Children and adults: VRE: 7.5 mg/kg q 8 hr IV for VRE; skin infections: 7.5 mg/kg q 12 hr IV | Adverse events: Pain, edema, or phlebitis at injection site, nausea, diarrhea  
Drug interactions: Synercid is a potent inhibitor of CYP 3A4 |
| **Sulfadiazine**  
Tablet: 500 mg | Sulfonamide antibiotic primarily indicated for the treatment of lower urinary tract infections caused by *E. coli*, *P. mirabilis*, and *Klebsiella*  
Toxoplasmosis  
Neonates: 100 mg/kg/24 hr divided q 12 hr PO with pyrimethamine 1 mg/kg/24 hr PO (with folinic acid)  
Children: 120-200 mg/kg/24 hr divided q 6 hr PO with pyrimethamine 2 mg/kg/24 hr divided q 12 hr PO ≥3 days then 1 mg/kg/24 hr (max dose: 25 mg/24 hr) with folinic acid  
Rheumatic fever prophylaxis: weight ≤30 kg: 500 mg/24 hr q 24 hr PO; weight >30 kg: 1 g/24 hr q 24 hr PO | Cautions: Rash, Stevens-Johnson syndrome, nausea, leukopenia, crystalluria. Renal and hepatic elimination; avoid use with renal disease. Half-life ~10 hr  
Drug interactions: Protein displacement with warfarin, phenytoin, methotrexate |
| **Sulfamethoxazole**  
Gantanol, Tablet: 500 mg  
Suspension: 500 mg/5 mL  
Ophthalmic solution, ointment | Sulfonamide antibiotic used for the treatment of otitis media, chronic bronchitis, and lower urinary tract infections due to susceptible bacteria  
Children: 50-60 mg/kg/24 hr divided q 12 hr PO  
Adults: 1 g/dose q 12 hr PO (max dose: 3 g/24 hr) | Cautions: Rash, Stevens-Johnson syndrome, nausea, leukopenia, crystalluria. Renal and hepatic elimination; avoid use with renal disease. Half-life 12 hr. Initial dose often a loading dose (doubled)  
Drug interactions: Protein displacement with warfarin, phenytoin, methotrexate |
| **Sulfisoxazole**  
Gantrisin, Tablet: 500 mg  
Suspension: 500 mg/5 mL  
Ophthalmic solution, ointment | Sulfonamide antibiotic used for the treatment of otitis media, chronic bronchitis, and lower urinary tract infections caused by susceptible bacteria  
Children: 120-150 mg/kg/24 hr divided q 4-6 hr PO  
Adults: 4-8 g/24 hr divided q 4-6 hr PO | Cautions: Rash, Stevens-Johnson syndrome, nausea, leukopenia, crystalluria. Renal and hepatic elimination; avoid use with renal disease. Half-life ~7-12 hr. Initial dose often a loading dose (doubled)  
Drug interactions: Protein displacement with warfarin, phenytoin, methotrexate |
| **Ticar**  
Ticarcillin, Injection | Extended-spectrum penicillin (ticarcillin) combined with a β-lactamase inhibitor (clavulanate) active against *S. aureus*, *H. influenzae*, *Enterobacter*, *E. coli*, *Serratia*, *P. aeruginosa*, *Acinetobacter*, and *Bacteroides*  
Children: 280-400 mg/kg/24 hr q 4-8 hr IV or IM  
Adults: 3.1 g q 4-8 hr IV or IM (max dose: 18-24 g/24 hr) | Cautions: β-Lactam safety profile (rash, eosinophilia); painful given intramuscularly; each gram contains 5-6 mEq sodium. Interferes with platelet aggregation; increases in liver function tests. Renally eliminated  
Drug interaction: Probencid |

Resistance to penicillin is mediated by a variety of mechanisms (see Table 180-1). The production of β-lactamase is a common mechanism exhibited by many organisms that may be overcome, with variable success, by including a β-lactamase inhibitor with the penicillin. Such combination products (ampicillin-sulbactam, amoxicillin-clavulanate, piperacillin-tazobactam) are potentially very useful for management of resistant isolates, but only if the resistance is β-lactamase mediated. Notably, S. aureus and S. pneumoniae mediate β-lactam resistance through mechanisms other than β-lactamase production, rendering these combination agents of little value for the management of β-lactam–resistant S. aureus and S. pneumoniae infections.

Table 180-4 lists adverse reactions to penicillins.

Cephalosporins

Cephalosporins differ structurally from penicillins insofar as the β-lactam ring exists as a 6-member ring, compared to the 5-member ring structure of the penicillins. These agents are widely used in pediatric practice, both in oral and parenteral formulations (Table 180-5). The first-generation cephalosporins (e.g., cefazolin, a parenteral formulation, and cefalexin, an oral equivalent) are commonly used for management of skin and soft-tissue infections caused by susceptible strains of S. aureus and group A Streptococcus. The second-generation cephalosporins (e.g., cefuroxime, cefoxitin) have better activity against Gram-negative bacterial infections than do first-generation cephalosporins and are used to treat respiratory tract infections, urinary tract infections, and skin and soft-tissue infections. A variety of orally administered second-generation agents (cefadroxil, cefprozil, loracarbef, cefpodoxime) are commonly used in the outpatient management of sinopulmonary infections and otitis media. The third-generation cephalosporins (cefotaxime, ceftriaxone, and cefazidime) are typically used for serious pediatric infections, including meningitis and sepsis. Cefazidime is highly active against most strains of

*All the reactions can occur with any of the penicillins.

P. aeruginosa, making this a useful agent for febrile, neutropenic oncology patients. Ceftriaxone should not be mixed or reconstituted with a calcium-containing product, such as Ringer or Hartmann solution or parenteral nutrition containing calcium, because particulate formation can result. Cases of fatal reactions with ceftriaxone–calcium precipitates in lungs and kidneys in neonates have been reported. A fourth-generation cephalosporin, called ceftazidime, has activity against P. aeruginosa and retains good activity against methicillin-susceptible staphylococcal infections. A fifth-generation cephalosporin, ceftolozane, has been approved for use in Canada and the European Union. Another novel cephalosporin with activity against P. aeruginosa, ceftolozane, is approaching licensure and will be combined with the β-lactamase inhibitor, tazobactam, in its final licensed formulation.

Table 180-6 lists adverse reactions to cephalosporins.

**Carbapenems**

The carbapenems include imipenem formulated in combination with cilastatin, meropenem, ertapenem, and doripenem. The basic structure of these agents is similar to that of β-lactam antibiotics, and these drugs have a similar mechanism of action. The carbapenems provide the broadest spectrum of anti-bacterial activity of any licensed class of antibiotics and are active against Gram-positive, Gram-negative, and anaerobic organisms. Among the carbapenems, meropenem is the only agent licensed for treatment of pediatric meningitis. At this time, ertapenem and doripenem are not approved for pediatric use. Importantly, MRSA and *E. faecium* are not susceptible to carbapenems. Carbapenems also tend to be poorly active against *Stenotrophomonas maltophilia*, rendering their use for cystic fibrosis patients who are infected with this organism problematic. Ertapenem is poorly active against *P. aeruginosa* and *Acinetobacter* species and should be avoided when these pathogens are encountered. Although imipenem–cilastatin is the first carbapenem approved for clinical use and the carbapenem with which there is the greatest clinical experience, this antibiotic unfortunately has a propensity to cause seizures in children, particularly in the setting of intercurrent meningitis. Accordingly, meropenem is typically more suitable for pediatric use, where meningitis is commonly a consideration.

Other carbapenems in various stages of clinical trials include panipenem, biapenem, razupenem, tomopenem, and tebipenem/pivoxil (the first oral carbapenem). Panipenem and biapenem are licensed in Japan, but there is minimal experience with pediatric dosing.

**Glycopeptides**

Glycopeptide antibiotics include vancomycin and teicoplanin, the less commonly available analog. These agents are bactericidal and act via inhibition of cell wall biosynthesis. The antimicrobial activity of the glycopeptides is limited to Gram-positive organisms, including *S. aureus*, coagulase-negative staphylococci, pneumococci, enterococci, *Bacillus*, and *Corynebacterium*. Vancomycin is frequently employed in pediatric practice and is of particular value for serious infections, including meningitis, caused by MRSA and penicillin- and cephalosporin-resistant *S. pneumoniae*. Vancomycin is also commonly used for infections in the setting of fever and neutropenia in oncology patients, in combination with other antibiotics (see Chapter 178), and for infections associated with indwelling medical devices (see Chapter 179). Oral formulations of vancomycin are occasionally used to treat pseudomembranous colitis caused by *Clostridium difficile* infections; intrathecal therapy may also be used for selected CNS infections. Vancomycin must be administered with care because of its propensity to produce red man syndrome, which is a reversible adverse effect that is rare in young children and can typically be readily managed by slowing the rate of infusion of the drug. Newer glycopeptides antibiotics include oritavancin, dalbavancin, and the glycolipodepsipeptide agent, ramoplanin. Telavancin has been approved by FDA for the treatment of skin and soft-tissue infections suspected or known to be caused by MRSA for situations where other alternatives are not suitable.

**Aminoglycosides**

Aminoglycoside antibiotics include streptomycin, kanamycin, gentamicin, tobramycin, netilmicin, and amikacin. The most commonly used aminoglycosides in pediatric practice are gentamicin and tobramycin. They exert their mechanism of action via inhibition of bacterial protein synthesis. Although they are most commonly used to treat Gram-negative infections, the aminoglycosides are broad-spectrum β-lactam antibiotics, they have a similar mechanism of action. The carbapenems provide the broadest spectrum of anti-bacterial activity of any licensed class of antibiotics and are active against Gram-positive, Gram-negative, and anaerobic organisms. Among the carbapenems, meropenem is the only agent licensed for treatment of pediatric meningitis. At this time, ertapenem and doripenem are not approved for pediatric use. Importantly, MRSA and *E. faecium* are not susceptible to carbapenems. Carbapenems also tend to be poorly active against *Stenotrophomonas maltophilia*, rendering their use for cystic fibrosis patients who are infected with this organism problematic. Ertapenem is poorly active against *P. aeruginosa* and *Acinetobacter* species and should be avoided when these pathogens are encountered. Although imipenem–cilastatin is the first carbapenem approved for clinical use and the carbapenem with which there is the greatest clinical experience, this antibiotic unfortunately has a propensity to cause seizures in children, particularly in the setting of intercurrent meningitis. Accordingly, meropenem is typically more suitable for pediatric use, where meningitis is commonly a consideration.

Other carbapenems in various stages of clinical trials include panipenem, biapenem, razupenem, tomopenem, and tebipenem/pivoxil (the first oral carbapenem). Panipenem and biapenem are licensed in Japan, but there is minimal experience with pediatric dosing.

**Glycopeptides**

Glycopeptide antibiotics include vancomycin and teicoplanin, the less commonly available analog. These agents are bactericidal and act via inhibition of cell wall biosynthesis. The antimicrobial activity of the glycopeptides is limited to Gram-positive organisms, including *S. aureus*, coagulase-negative staphylococci, pneumococci, enterococci, *Bacillus*, and *Corynebacterium*. Vancomycin is frequently employed in pediatric practice and is of particular value for serious infections, including meningitis, caused by MRSA and penicillin- and cephalosporin-resistant *S. pneumoniae*. Vancomycin is also commonly used for infections in the setting of fever and neutropenia in oncology patients, in combination with other antibiotics (see Chapter 178), and for infections associated with indwelling medical devices (see Chapter 179). Oral formulations of vancomycin are occasionally used to treat pseudomembranous colitis caused by *Clostridium difficile* infections; intrathecal therapy may also be used for selected CNS infections. Vancomycin must be administered with care because of its propensity to produce red man syndrome, which is a reversible adverse effect that is rare in young children and can typically be readily managed by slowing the rate of infusion of the drug. Newer glycopeptides antibiotics include oritavancin, dalbavancin, and the glycolipodepsipeptide agent, ramoplanin. Telavancin has been approved by FDA for the treatment of skin and soft-tissue infections suspected or known to be caused by MRSA for situations where other alternatives are not suitable.

**Aminoglycosides**

Aminoglycoside antibiotics include streptomycin, kanamycin, gentamicin, tobramycin, netilmicin, and amikacin. The most commonly used aminoglycosides in pediatric practice are gentamicin and tobramycin. They exert their mechanism of action via inhibition of bacterial protein synthesis. Although they are most commonly used to treat Gram-negative infections, the aminoglycosides are broad-spectrum β-lactam antibiotics, they have a similar mechanism of action. The carbapenems provide the broadest spectrum of anti-bacterial activity of any licensed class of antibiotics and are active against Gram-positive, Gram-negative, and anaerobic organisms. Among the carbapenems, meropenem is the only agent licensed for treatment of pediatric meningitis. At this time, ertapenem and doripenem are not approved for pediatric use. Importantly, MRSA and *E. faecium* are not susceptible to carbapenems. Carbapenems also tend to be poorly active against *Stenotrophomonas maltophilia*, rendering their use for cystic fibrosis patients who are infected with this organism problematic. Ertapenem is poorly active against *P. aeruginosa* and *Acinetobacter* species and should be avoided when these pathogens are encountered. Although imipenem–cilastatin is the first carbapenem approved for clinical use and the carbapenem with which there is the greatest clinical experience, this antibiotic unfortunately has a propensity to cause seizures in children, particularly in the setting of intercurrent meningitis. Accordingly, meropenem is typically more suitable for pediatric use, where meningitis is commonly a consideration.

streptococci, corynebacteria JK, Pseudomonas, Staphylococcus epidermidis, and Enterococcus when coadministered with a β-lactam agent. Aminoglycoside use has decreased with the development of newer alternatives, but they still play a key role in pediatric practice in the management of neonatal sepsis, urinary tract infections, Gram-negative sepsis, and complicated intraabdominal infections; infections in cystic fibrosis patients (including both parenteral and aerosolized forms of therapy); and in oncology patients with fever and neutropenia. Aminoglycosides, in particular streptomycin, are also important in the management of Francisella tularensis, Mycobacterium tuberculosis, and atypical mycobacterial infections. Toxicities of aminoglycoside therapy include nephrotoxicity and otoxicity (cochlear and/or vestibular), and serum levels as well as renal function and hearing should be monitored for patients on long-term therapy. Toxicities of aminoglycosides may be reduced by the use of once-daily dosing regimens with appropriate monitoring of serum levels. Hypokalemia, volume depletion, hypomagnesemia, and other nephrotoxic drugs may increase the renal toxicity of aminoglycosides. A rare complication of aminoglycosides is neuromuscular blockade, which may occur in the presence of other neuromuscular blocking agents and in the setting of infant botulism.

Tetracyclines

The tetracyclines (tetracycline hydrochloride, doxycycline, demeclocycline, and minocycline) are bacteriostatic antibiotics that exhibit their antimicrobial effect by binding to the bacterial 30S ribosomal subunit, inhibiting protein translation. These agents have a broad spectrum of antimicrobial activity against Gram-positive and Gram-negative bacteria, rickettsia, and some parasites. The oral bioavailability of these agents facilitates oral dosing for many infections, including Rocky Mountain spotted fever, ehrlichiosis, Lyme disease, and malaria. Tetracyclines must be prescribed judiciously to children younger than 9 yr of age, because they can cause staining of teeth, hypoplasia of dental enamel, and abnormal bone growth in this age group. Tigecycline, a semisynthetic derivative of minocycline, is licensed in the United States. It is a parenteral agent of a new class of antibiotics (glycyclines). It has a broader spectrum of activity (bacteriostatic) than traditional tetracyclines, but retains the side–effect profile of tetracyclines. Tigecycline is active against tetracycline-resistant Gram-positive and Gram-negative pathogens, including MRSA, and possibly VRE, but not Pseudomonas.

Complications of tetracyclines include eosinophilia, leukopenia and thrombocytopenia (tetracycline), pseudotumor cerebri, anorexia, emesis and nausea, candidal superinfection, hepatitis, photosensitivity, and a hypersensitivity reaction (urticaria, asthma exacerbation, facial edema, dermatitis) as well as a systemic lupus erythematosus–like syndrome (minocycline). The FDA issued a black box warning regarding tigecycline in 2013 based on a meta-analysis of 10 studies that showed increased mortality among patients receiving this drug. A salutary side effect of demeclocycline has been identified: it is occasionally used as an off-label treatment of hyponatremia resulting from the syndrome of inappropriate antidiuretic hormone.

Sulfonamides

Trimethoprim and the sulfonamides are bacteriostatic agents that inhibit the bacterial folate synthesis pathway, in the process impairing both nucleic acid and protein synthesis. Sulfonamides interfere with the synthesis of dihydropteroic acid from paraaminobenzoic acid, whereas trimethoprim acts at a site further downstream, interfering with synthesis of tetrahydrofolic acid from dihydrofolic acid. The sulfonamides are available in both parenteral and oral formulations. Although there have historically been a large number of sulfonamide antibiotics developed for clinical use, relatively few remain available for pediatric practice. The most important agent is the combination of trimethoprim-sulfamethoxazole (TMP-SMZ), which is commonly used for treatment of urinary tract infections. TMP-SMZ has also emerged as a commonly prescribed agent for staphylococcal skin and soft-tissue infections, since this antibiotic retains activity against MRSA. TMP-SMZ also plays a unique role in immunocompromised patients, as a prophylactic and therapeutic agent for Pneumocystis jiroveci infection. Other commonly used sulfonamides include sulfisoxazole, which is useful in the management of urinary tract infections, and sulfadiazine, which is a drug of choice in the treatment of toxoplasmosis.

Macrolides

The macrolide antibiotics most commonly used in pediatric practice include erythromycin and the newer agents, clarithromycin and azithromycin. This class of antimicrobials exerts its antibiotic effect through binding to the 50S subunit of the bacterial ribosome, producing a block in elongation of bacterial polypeptides. Clarithromycin is metabolized to 14-hydroxy clarithromycin, and interestingly this active metabolite also has potent antiinfectious activity. The spectrum of antiinfectious activity includes many Gram-positive bacteria. Unfortunately, resistance to these agents among S. aureus and group A Streptococcus is fairly widespread, limiting the usefulness of macrolides for many skin and soft-tissue infections and for streptococcal pharyngitis. Azithromycin and clarithromycin have demonstrated efficacy for otitis media. All of the members of this class have an important role in the management of pediatric respiratory infections, including atypical pneumonias caused by M. pneumoniae, Chlamydia pneumoniae, and Legionella pneumophila, as well as infections caused by Bordetella pertussis.

Telithromycin is a ketolide antibiotic derived from erythromycin. It was initially approved by the FDA for the treatment in adults of mild to moderate community-acquired pneumonia, acute exacerbations of chronic bronchitis, and acute sinusitis, having good activity against the agents causing these infections (S. pneumoniae, M. pneumoniae, C. pneumoniae, and L. pneumophila for community-acquired pneumonia; M. catarrhalis and H. influenzae for sinusitis). Reports of liver failure and myasthenia gravis from telithromycin in particular prompted the withdrawal of the indication for sinusitis and bronchitis by the FDA.

Drug interactions are common with erythromycin and telithromycin and to a lesser extent with clarithromycin. These agents can inhibit the CYP 3A4 enzyme system, resulting in increased levels of certain drugs such as astemizole, cisapride, statins, pimozide, and theophylline. Itraconazole may increase macrolide levels, while rifampin, carbamazepine, and phenytoin may decrease macrolide levels. There are few reported adverse drug interactions with azithromycin. Cross-resistance may develop between a macrolide and the subsequent use of clindamycin.

Lincosamides

The prototype of the lincosamide class of antibiotics is clindamycin, which acts at the ribosomal level to exert its antimicrobial effect. The 50S subunit of the bacterial ribosome is the molecular target of this agent. Its spectrum of activity includes Gram-positive aerobes and anaerobes. Clindamycin has no significant activity against Gram-negative organisms. An important role for clindamycin has emerged in the management of MRSA infections. Because of its outstanding penetration into body fluids (excluding the CNS) and tissues and bone, clindamycin can be utilized for therapy of serious infections caused by MRSA. Clindamycin is also useful in the management of invasive group A Streptococcus infections and in the management of many anaerobic infections, often in combination with a β-lactam. There is a form of inducible clindamycin resistance exhibited by some strains of MRSA; therefore, consultation with the clinical microbiology laboratory is necessary before treating a serious MRSA infection with clindamycin. Pseudomembranous colitis, a complication of clindamycin therapy commonly encountered in adults, is seldom observed in pediatric patients. Clindamycin also plays an important role in the treatment of malaria and babesiosis (when coadministered with quinine), P. jiroveci pneumonia (when coadministered with primaquine), and toxoplasmosis.

Quinolones

The fluoroquinolones (ciprofloxacin, levofloxacin, moxifloxacin, gemifloxacin, besifloxacin) are antimicrobials that inhibit bacterial DNA replication by binding to the topoisomerases of the target pathogen, inhibiting the bacterial enzyme DNA gyrase. This class has very broad-spectrum activity against both Gram-positive and Gram-negative organisms. Some of the fluoroquinolones exhibit activity against penicillin-resistant S. pneumoniae as well as MRSA. These agents uniformly exhibit excellent activity against Gram-negative pathogens, including the Enterobacteriaceae and respiratory tract pathogens such as M. catarrhalis and H. influenzae. Quinolones are also very active against pathogens associated with atypical pneumonia, particularly M. pneumoniae and L. pneumophila.

Although these agents are not approved for use in children, there is a reasonable body of evidence that the fluoroquinolones are generally safe, well tolerated, and effective against a variety of bacterial infections commonly encountered in pediatric practice. Parenteral quinolones are appropriate for critically ill patients with Gram-negative infections. The use of oral quinolones in stable outpatients may also be reasonable for treatment of infections that would otherwise require parenteral antibiotics (P. aeruginosa soft-tissue infections such as osteochondritis) or selected genitourinary tract infections. However, they should be reserved for situations where no other oral antibiotic alternative is feasible. In 2013, the FDA announced that it was changing the warning labels for fluoroquinolones to more adequately describe the risk of permanent peripheral neuropathy associated with this class of antimicrobials. Additional risks include arrhythmias and retinal detachment. Moreover, in situations of overdose (such as typhoid fever and gonococcal infection), organisms have been demonstrated to rapidly develop resistance. Thus, the use of fluoroquinolones in pediatric practice should still be approached with continued caution, and consultation with an expert is recommended.

Streptogramins and Oxazolidinones

The emergence of highly resistant Gram-positive organisms, in particular VRE, has necessitated development of new classes of antibiotics.
One such class that is especially useful for resistant Gram-positive infections is the streptogramins. The currently licensed agent in this category is dalfopristin-quinupristin, which is available in a parenteral formulation. It is appropriate for treatment of MRSA, coagulase-negative staphylococci, penicillin-susceptible and penicillin-resistant S. pneumoniae, and vancomycin-resistant E. faecium but not E. faecalis.

Another licensed class of antibiotics for highly resistant Gram-positive infections is the oxazolidinone class. The prototype in this group is linezolid, which is available in both oral and parenteral formulations and is approved for use in pediatric patients. Its mechanism of action involves inhibition of ribosomal protein synthesis. It is indicated for MRSA, VRE, coagulase-negative staphylococci, and penicillin-resistant S. pneumoniae. There is little information on dalfopristin-quinupristin and linezolid in treatment of CNS infections, and neither agent is approved for pediatric meningitis. Linezolid can cause anemia and thrombocytopenia and is a monoamine oxidase inhibitor.

Daptomycin
Daptomycin is a novel member of the cyclic lipopeptide class of antibiotics. Its spectrum of activity includes virtually all Gram-positive organisms, including E. faecalis and E. faecium (including VRE) and S. aureus (including MRSA). The structure of daptomycin is a 13-member amino acid peptide linked to a 10-carbon lipophilic tail, which results in a novel mechanism of action of disruption of the bacterial membrane through the formation of transmembrane channels. These channels cause leakage of intracellular ions, leading to depolarization of the cellular membrane and inhibition of macromolecular synthesis. A theoretical advantage of daptomycin for serious infections is its bactericidal activity against MRSA and enterococci. It is administered IV. Experience in children is limited. Myopathy and elevations in creatine phosphokinase have been described. An FDA warning has been issued linking some cases of eosinophilic pneumonitis to the use of daptomycin. Daptomycin is inactivated by surfactant and should not be used to treat pneumonia.

Miscellaneous Agents
Although rarely used today because of safety concerns and limited availability, chloramphenicol occasionally plays a role in the management of pediatric infections, particularly those involving the CNS. This agent binds peptidyl transferase, a component of the 50S ribosome, inhibiting bacterial protein synthesis. Metronidazole, which functions by disruption of DNA synthesis, has a unique role as an antianaerobic agent and also possesses antiparasitic and anthelmintic activity. Rifampin is a rifamycin antibiotic that inhibits bacterial RNA polymerase and has a major role in the management of tuberculosis. It is also of value in the management of other bacterial infections in pediatric patients, usually used as a second (synergistic) agent in the treatment of S. aureus infections or to eliminate nasopharyngeal colonization of H. influenzae type b or N. meningitidis. Rifaximin is a nonabsorbed rifamycin that has been used as an adjunct agent to treat patients with multiple recurrences of C. difficile infection. The emerging crisis in antimicrobial resistance has also necessitated the “rediscovery” of antimicrobial agents seldom used in clinical practice in recent decades, such as colistin (colistimethate sodium). This agent is a member of the polymyxin family of antibiotics (polymyxin E). Polymyxins have a general structure consisting of a cyclic peptide with hydrophobic tails. After binding to lipopolysaccharide in the outer membrane of Gram-negative bacteria, polymyxins disrupt both the outer and inner membranes, leading to cell death. Colistin is broadly active against the Enterobacteriaceae family, including P. aeruginosa. It is also active against extended-spectrum β-lactamase- and carbapenemase-producing strains. Toxicities are chiefly renal and neurologic.

Bibliography is available at Expert Consult.
Bibliography

Staphylococci are hardy, aerobic, Gram-positive bacteria that grow in pairs and clusters and are ubiquitous as normal flora of humans and present on fomites and in dust. They are resistant to heat and drying and may be recovered from nonbiologic environments weeks to months after contamination. Strains are classified as *Staphylococcus aureus* if they are coagulase positive or as 1 of the many species of coagulase-negative staphylococci (e.g., *Staphylococcus epidermidis*, *Staphylococcus saprophyticus*, *Staphylococcus haemolyticus*, etc.). Often, *S. aureus* produces a yellow or orange pigment and β-hemolysis on blood agar and *S. epidermidis* produces a white pigment with variable hemolysis results, although definitive species confirmation requires further testing. *S. aureus* has many virulence factors that mediate various serious diseases, whereas coagulase-negative staphylococci tend to be less pathogenic unless an indwelling foreign body (e.g., intravascular catheter) is present. Since 2000, *S. aureus* strains resistant to β-lactam antibiotics, commonly referred to as methicillin-resistant *S. aureus* (MRSA) have become a significant problem in both community and hospital settings. Vancomycin resistance is rare, but MRSA have been reported with an elevated vancomycin minimal inhibitory concentration (≥ 1.5 mg/L).

### ETIOLOGY

Strains of *S. aureus* can be identified and characterized by the virulence factors they produce. These factors tend to play 1 or more of 4 pathogenic roles in human disease: *S. aureus* protecting the organism from host defenses, localizing infection, causing local tissue damage, and affecting noninfected sites through toxin elaboration.

Most strains of *S. aureus* possess factors that protect the organism from host defenses. Many staphylococci produce a loose polysaccharide capsule, or slime layer, which may interfere with opsonophagocytosis. Production of clumping factor and/or coagulase differentiates *S. aureus* from coagulase-negative staphylococci. Clumping factor interacts with fibrinogen to cause large clumps of organisms, interfering with effective phagocytosis. Coagulase causes plasma to clot by interacting with fibrinogen and this may have an important role in localization of infection (abscess formation). Protein A is present in most strains of *S. aureus* but not coagulase-negative staphylococci and reacts specifically with immunoglobulin G (IgG1, IgG2, and IgG4). It is
located on the outermost coat of the cell wall and can absorb serum immunoglobulins, preventing antibacterial antibodies from acting as opsonins and thus inhibiting phagocytosis. Other enzymes elaborated by staphylococci include catalase (inactivates hydrogen peroxide, promoting intracellular survival), penicillinase or β-lactamase (inactivates penicillin at the molecular level), and lipase (associated with skin infection).

Many strains of *S. aureus* produce substances that cause local tissue destruction. A number of immunologically distinct hemolysins that act on cell membranes and cause tissue necrosis have been identified (β-toxin, β-hemolysin, δ-hemolysin). Much attention has been given to the Panton-Valentine leukocidin, a protein that *S. aureus* combines with phospholipid in the leukocytic cell membrane, producing increased permeability and eventual death of the cell. Strains of *S. aureus* that produce Panton-Valentine leukocidin are associated with more-severe and invasive skin disease, pneumonia, and osteomyelitis. Many strains of *S. aureus* release 1 or more exotoxins. *Exfoliatois A and B* are serologically distinct proteins that produce localized (bullous impetigo) or generalized (scalded skin syndrome, staphylococcal scarlet fever) dermatologic manifestations (see Chapter 659). Exfoliatois produce skin separation by splitting the desmosome and altering the intracellular matrix in the stratum granulosum. *S. aureus* can produce more than 20 distinct enterotoxins (types A-V). Ingestion of preformed enterotoxin, particularly types A or B, can result in *food poisoning*, resulting in vomiting and diarrhea and, in some cases, profound hypotension. By 10 yr of age, almost all individuals have antibodies to at least 1 enterotoxin. *Toxic shock syndrome toxin-1 (TSST-1)* is associated with *S. aureus* related to menstruation and focal staphylococcal infection. TSST-1 is a superantigen that induces production of interleukin-1 and tumor necrosis factor, resulting in hypotension, fever, and multisystem involvement. Enterotoxins A and B also may be associated with non-menstrual TSS.

*S. aureus* also possesses intrinsic factors that can contribute to pathogenesis, including *teichoic acid* in the cell wall, which mediates adhesion to mucosal cells proteins that promote adhesion to fibronectin, fibronectin, collagen, and other human proteins. Expression of proteins that mediate antibiotic resistance is also of critical importance. Though historically sensitive to penicillin, *S. aureus* isolates now almost universally produce penicillinase, an enzyme that disrupts the β-lactam structure of penicillin. Production of altered penicillin-binding proteins (PBP)s in the bacterial cell wall mediates resistance to penicillinase resistant antibiotics; an *altered PBP-2A* is responsible for the methicillin resistance of MRSA isolates. MRSA strains appear to be at least as virulent as their methicillin-sensitive counterparts.

**Epidemiology**

Approximately 20-40% of normal individuals carry at least 1 strain of *S. aureus* in the anterior nares at any given time, with intermittent carriage occurring in up to 70% of individuals. The organisms may be transmitted from the nose to the skin, where colonization is more transient. Persistent umbilical, vaginal, and perianal carriage may also occur. Many neonates are colonized within the 1st wk of life. Rates of colonization with MRSA in the general population are typically less than 2% but have increased since 2000. MRSA colonization rates greater than 20-30% have been reported in higher risk populations with significant healthcare exposure.

Exposure to *S. aureus* generally occurs by autoinoculation or direct contact with the hands of other colonized individuals. Heavily colonized nasal carriers (often aggravated by a viral upper respiratory tract infection) are particularly effective disseminators. Spread via fomites is rare, though an outbreak occurring in a high school football team was attributed to sharing towels. Infection control policies in health-care facilities, particularly those emphasizing good hand hygiene, have been shown to decrease rates of nosocomial staphylococcal infection. Outside of the hospital setting, outbreaks of staphylococcal disease, in particular disease due to methicillin-resistant strains, have been reported among athletes, military personnel, young children, veterinarians, injection drug users, and inmates in correctional facilities. Increased disease frequency is noted among household contacts of a MRSA colonized or infected individual. Skin infections caused by *S. aureus* are considerably more prevalent among persons living in low socioeconomic circumstances and particularly among those in tropical climates.

The burden of staphylococcal disease is significant. Most important is the role of *S. aureus*, including MRSA, in hospital acquired infections, including infections of the bloodstream, infection of surgical sites, and ventilator-associated pneumonia. *S. aureus* is a significant cause of morbidity and mortality in neonatal intensive care units. Two population-based studies suggested a decline in rates of MRSA-related hospital-acquired infection, possibly reflecting the benefits of aggressive infection control procedures.

Community-acquired staphylococcal infections are estimated to result in 14 million outpatient healthcare visits. In 2005 an estimated 478,000 hospitalizations were associated with *S. aureus* infection in the United States, over half of which were caused by MRSA.

**Pathogenesis**

Except in the case of food poisoning resulting from ingestion of preformed enterotoxins, disease associated with *S. aureus* typically begins with colonization as described above. Subsequent disease manifestations in susceptible individuals results either directly from tissue invasion or injury caused by various toxins and enzymes produced by the organism (Fig. 181-1).

The most significant risk factor for the development of infection is disruption of intact skin, including breaches from wounds, skin disease such as eczema, epidermolysis bullosa or burns, ventriculoperitoneal shunts, and indwelling intravascular or intrathecal catheters. Additional risk factors include corticosteroid treatment, malnutrition, shunts, and indwelling intravascular or intrathecal catheters. Addi

**CLINICAL MANIFESTATIONS**

Signs and symptoms vary with the location of the infection, which is most commonly the skin but may be any tissue. Disease states of various degrees of severity are generally a result of local suppuration, systemic dissemination with metastatic infection, or systemic effects of toxin production.

**Newborn**

*S. aureus* is an important cause of neonatal infections (see Chapter 109.5).

**Skin**

*S. aureus* is an important cause of pyogenic skin infections, including impetigo contagiosa, eczema, bullous impetigo, folliculitis, hydredinitis, furuncles (boils), carbuncles (multiple coalesced boils), paronychia, staphylococcal scalded skin syndrome, and staphylococcal scarlet fever. Infection may also cause superinfection of other noninfectious skin disease, for example, eczema, or bug bites. Recurrent furunculosis is associated with repeated episodes of pyoderma over months to years. Recurrent skin and soft-tissue infections are commonly noted with community-associated MRSA and often affect the lower extremities and buttocks. *S. aureus* is also an important cause of traumatic and surgical wound infections and can cause deep soft-tissue involvement, including cellulitis and rarely necrotizing fasciitis.

**Respiratory Tract**

Infections of the upper respiratory tract (otitis media, sinusitis) caused by *S. aureus* are rare, in particular considering the frequency with which the anterior nares are colonized. *S. aureus* sinusitis is relatively common in children with cystic fibrosis or defects in leukocyte function and may be the only focus of infection in some children with TSS. Suppurative parotitis is a rare infection, but *S. aureus* is a common cause of this infection. A membranous tracheitis that complicates viral croup may be a result of infection with *S. aureus*, but other organisms are also possible. Patients typically have high fever, leukocytosis, and evidence of severe upper airway obstruction. Direct laryngoscopy or bronchoscopy shows a normal epiglottis with subglottic narrowing and thick, purulent secretions within the trachea. Treatment requires careful airway management and appropriate antibiotic therapy.

Pneumonia (see Chapter 400) caused by *S. aureus* may be primary or secondary after a viral infection such as influenza. Hematogenous pneumonia may be secondary to septic emboli from right-sided endocarditis or septic thrombophlebitis, with or without the presence of intravascular devices. Inhalation pneumonia is caused by alteration of mucociliary clearance, leukocyte dysfunction, or bacterial adherence initiated by a viral infection. Common symptoms and signs include high fever, abdominal pain, tachypnea, dyspnea, and localized or diffuse bronchopneumonia or lobar disease. *S. aureus* often causes a necrotizing pneumonitis that may be associated with early development of empyema, pneumatoceles, pyopneumothorax, and bronchopleural fistulas.

**Sepsis**

*S. aureus* bacteremia and sepsis may be primary or associated with any localized infection. The onset may be acute and marked by nausea, vomiting, myalgia, fever, and chills. Organisms may localize subsequently at any site (usually a single deep focus) but are found especially in the heart valves, lungs, joints, bones, muscles, and deep tissue abscesses.

In some instances, especially in young adolescent males, disseminated *S. aureus* disease occurs, characterized by fever, persistent bacteremia despite antibiotics, and focal involvement of 2 or more separate tissue sites (skin, bone, joint, kidney, lung, liver, heart). In these cases, endocarditis and septic thrombophlebitis must be ruled out. All patients with primary *S. aureus* bacteremia, especially those with persistently positive blood cultures should be evaluated for endocarditis with transthoracic, and if that is negative, transesophageal, echocardiography.

**Muscle**

Localized staphylococcal abscesses in muscle sometimes without septicemia have been called pyomyositis. This disorder is reported most frequently from tropical areas and is termed tropical pyomyositis, but also occurs frequently in the United States in otherwise healthy children. Multiple abscesses occur in 30-40% of cases. History may include prior trauma at the site of the abscess. Surgical drainage and appropriate antibiotic therapy are essential.

**Bones and Joints**

*S. aureus* is the most common cause of osteomyelitis and suppurrative arthritis in children (see Chapters 684 and 685).

**Central Nervous System**

Meningitis (see Chapter 603.1) caused by *S. aureus* is not common; it is associated with penetrating cranial trauma and neurosurgical procedures (cricotomy, cerebrospinal fluid [CSF] shunt placement), and less frequently with endocarditis, parameningeal foci (epidural or brain abscess), diabetes mellitus, or malignancy. The CSF profile of *S. aureus* meningitis is indistinguishable from that in other forms of bacterial meningitis.

**Heart**

*S. aureus* is a common cause of acute endocarditis (see Chapter 437) on native valves, and results in high rates of morbidity and mortality. Perforation of heart valves, myocardial abscesses, heart failure, conduction disturbances, acute hemopericardium, purulent pericarditis, and sudden death may ensue.

**Kidney**

*S. aureus* is a common cause of renal and perinephric abscess (see Chapter 538), usually of hematogenous origin. Pyelonephritis and cystitis caused by *S. aureus* are unusual.

**Toxic Shock Syndrome**

*S. aureus* is the principal cause of TSS (see Chapter 181.2), which should be suspected in anyone with fever, shock, and/or a scarlet fever-like rash.

**Intestinal Tract**

Staphylococcal enterocolitis rarely follows overgrowth of normal bowel flora by *S. aureus*, which can occur as a result of broad-spectrum oral antibiotic therapy. Diarrhea is associated with blood and mucus. Peritonitis associated with *S. aureus* in patients receiving long-term ambulatory peritoneal dialysis usually involves the catheter tunnel. Removal of the catheter is required to achieve a bacteriologic cure.

**Food poisoning** (see Chapter 340) may be caused by ingestion of preformed enterotoxins produced by staphylococci in contaminated foods. The source of contamination is often colonized or infected food workers. Approximately 2-7 hr after ingestion of the toxin, sudden, severe vomiting begins. Watery diarrhea may develop, but fever is absent or low. Symptoms rarely persist longer than 12-24 hr. Rarely, shock and death may occur.

**DIAGNOSIS**

The diagnosis of *S. aureus* infection depends on isolation of the organism from nonpermissive sites such as cellulitis aspirates, abscess cavities, blood, bone or joint aspirates, or other sites of infection. Swab cultures of surfaces are not as useful, as they may reflect surface contamination rather than the true cause of infection. Tissue samples or fluid aspirates in a syringe provide the best culture material. Cellulitic lesions are ideally cultured using a needle aspirate from the most inflamed area, inoculated directly into a blood culture bottle; use of injected saline and targeting the leading edge are less effective. Isolation from the nose or skin does not necessarily imply causation because these sites may be normally colonized sites. Because of the high prevalence of MRSA, the increasing severity of *S. aureus* infections, and the fact that bacteremia is not universally present even in severe *S. aureus* infections, it is important to obtain a nonpermissive culture of any...
potential focus of infection as well as a blood culture prior to starting antibiotic treatment. The organism can be grown readily in liquid and on solid media. After isolation, identification is made on the basis of Gram stain and coagulase, clumping factor, and protein A reactivity. Patterns of susceptibility to antibiotics should be assessed in serious cases, as antimicrobial resistance is increasingly common. Identification of MRSA infection or colonization has become increasingly important, from both a therapeutic and infection control standpoint. Inoculation of samples onto selective (e.g., cefoxitin-containing) media or use of latex agglutination to identify altered PBP-2a in positive cultures are 2 commonly used methods. Molecular (polymerase chain reaction) techniques are being used increasingly for the rapid identification of colonized patients on admission to the hospital or intensive care unit. Polymerase chain reaction for ribosomal RNA is emerging as an alternative for identifying bacterial pathogens and may eventually complement or replace traditional culture methods.

Diagnosis of S. aureus food poisoning is usually made on the basis of epidemiologic and clinical findings. Food suspected of contamination may be cultured and can be tested for enterotoxin.

**Differential Diagnosis**

Many of the clinical entities discussed above can also be caused by other bacterial pathogens, and consideration of the differential is particularly important when making empiric antibiotic choices prior to definitive identification of the offending pathogen. Skin lesions caused by S. aureus may be indistinguishable from those caused by group A streptococci, although the former usually expand slowly, while the latter are prone to spread more rapidly and can be very aggressive. Fluctuant skin and soft-tissue lesions also can be caused by other organisms, including *Mycobacterium tuberculosis*, atypical mycobacteria, *Bartonella henselae* (cat-scratch disease), *Francisella tularensis*, and various fungi, among others. Noncavitary S. aureus pneumonia can be difficult to differentiate from more common etiologies, although children with S. aureus are generally more ill. S. aureus pneumonia is often suspected after failure to improve on standard treatment which does not cover *Staphylococcus*, or on the basis of chest roentgenograms that reveal pneumatoceles, pyopneumothorax, or lung abscesses (Fig. 181-2). Other etiologies of cavitary pneumonias include *Klebsiella pneumoniae* and *M. tuberculosis*. In bone and joint infections, culture is the only way to differentiate S. aureus from other less-common etiologies including group A streptococci and in young children, *Kingella kingae*.

**TREATMENT**

Antibiotic therapy alone is rarely effective in individuals with undrained abscesses or with infected foreign bodies. Loculated collections of purulent material should be relieved by incision and drainage. Foreign bodies should be removed, if possible. Therapy always should be initiated with an antibiotic consistent with the local staphylococcal susceptibility patterns as well as the severity of infection. For most patients with serious *S. aureus* infection, intravenous treatment is recommended until the patient has become afebrile and other signs of infection have improved. Oral therapy is often continued for a period of time, especially in patients with chronic infection or undergoing host defense problems. Serious *S. aureus* infections, with or without abscesses, tend to persist and recur, necessitating prolonged therapy.

The antibiotic used as well as the dose, route, and duration of treatment depend on the site and severity of infection, the response of the patient to treatment, and the susceptibility of the organisms recovered. Treatment of *S. aureus* osteomyelitis (see Chapter 684), meningitis (see Chapter 603.1), and endocarditis (see Chapter 437) is discussed in the respective chapters on these diagnoses.

Initial treatment for serious infections thought to be caused by methicillin-susceptible *S. aureus* (MSSA) should include semisynthetic penicillin (e.g., nafcillin) or a first-generation cephalosporin (e.g., cefazolin). Penicillin and ampicillin are not appropriate, because more than 90% of all staphylococci isolated, regardless of source, are resistant to these agents. Addition of a β-lactamase inhibitor (clavulanic acid, sulbactam, tazobactam) to a penicillin-based drug also confers anti-staphylococcal activity but has no effect on MRSA. The spectrum of these agents (which includes Gram-negative bacteria) can be an advantage when broad empiric coverage is needed, but more narrow coverage should be selected once *S. aureus* is identified. Antistaphylococcal penicillins and cephalosporins do not provide activity against MRSA. For initial treatment for penicillin-allergic individuals and those with suspected serious infections caused by MRSA, vancomycin can be used. Serum levels of vancomycin should be monitored, with serum trough concentrations of 10–20 µg/mL, depending on the case. Many, but not all MSSA and community-acquired MRSA strains are susceptible to clindamycin, and initial treatment with IV clindamycin, followed by a transition to oral clindamycin has been effective in bone, joint, and soft-tissue infection. Inducible clindamycin resistance in isolates initially reported as susceptible must be ruled out by D-test or molecular methods. Clindamycin is bacteriostatic and should not be used to treat endocarditis, brain abscess, or meningitis caused by *S. aureus*. Given that the mechanism of action of clindamycin involves inhibition or protein synthesis, many experts use clindamycin to treat *S. aureus* toxin–mediated illnesses (TSS) to inhibit toxin production. MRSA is also resistant to carbapenems and is unreliably susceptible to the quinolones. Rare vancomycin intermediate and vancomycin-resistant strains of *S. aureus* have also been reported, mostly in patients being treated with vancomycin. Linezolid, daptomycin, and

---

**Figure 181-2 Pneumatocele formation.** A, A 5 yr old child with *Staphylococcus aureus* pneumonia initially demonstrated consolidation of the right middle and lower zones. B, Seven days later, multiple lucent areas are noted as pneumatoceles develop. C, Two weeks later, significant resolution is evident, with a rather thick-walled pneumatocele persisting in the right midzone associated with significant residual pleural thickening. (From Kuhn JP, Slovis TL, Haller JO; Caffey’s pediatric diagnostic imaging, ed 10. Philadelphia, 2004, Mosby, pp. 1003–1004.)
Vancomycin (15 mg/kg Q6-H + nafcillin or oxacillin)

Vancomycin (15 mg/kg Q8H)

Clindamycin

Nafcillin or oxacillin†

Cefazolin

Clindamycin

Vancomycin

Ampicillin + sulbactam

Vancomycin + gentamicin†

Trimethoprim-sulfamethoxazole

Linezolid‡

Quinupristin-dalfopristin‡

Fluoroquinolones

Vancomycin + gentamicin†

Clindamycin (if strain susceptible)

Trimethoprim-sulfamethoxazole

Vancomycin

For life-threatening infections (i.e., septicemia, endocarditis, CNS infection); linezolid could be substituted if the patient has received several recent courses of vancomycin

For non–life-threatening infection without signs of severe sepsis (e.g., skin infection, cellulitis, osteomyelitis, pyarthrosis) when rates of MRSA colonization and infection in the community are substantial

For non–life-threatening infection without signs of severe sepsis when rates of MRSA colonization and infection in the community are substantial and prevalence of clindamycin resistance is low

Not recommended for people younger than 18 yr of age or as monotherapy

For life-threatening infections

For pneumonia, septic arthritis, osteomyelitis, skin or soft tissue infections

For skin or soft tissue infections

Dependent on in vitro susceptibility test results

†One of the adjunctive agents, gentamicin or rifampin, should be added to the therapeutic regimen for life-threatening infections such as endocarditis or CNS infection or infections with a vancomycin-intermediate S. aureus strain. Consultation with an infectious diseases specialist should be considered to determine which agent to use and duration of use.

‡Linezolid, quinupristin-dalfopristin, and tigecycline are agents with activity in vitro and efficacy in adults with multidrug-resistant, Gram-positive organisms, including S. aureus. Because experience with these agents in children is limited, consultation with an infectious diseases specialist should be considered before use.

§Daptomycin is active in vitro against multidrug-resistant, Gram-positive organisms, including S. aureus, but has not been evaluated in children. Daptomycin is approved by the US FDA only for the treatment of complicated skin and skin structure infections and for S. aureus bloodstream infections. Daptomycin is ineffective for treatment of pneumonia and is not indicated for patients 18 yr of age and older.
PROGNOSIS
Untreated *S. aureus* septicemia is associated with a high fatality rate, which has been reduced significantly by appropriate antibiotic treatment. *S. aureus* pneumonia can be fatal at any age but is more likely to be associated with high morbidity and mortality in young infants or in patients whose therapy has been delayed. Prognosis also may be influenced by numerous host factors, including nutrition, immunologic competence, and the presence or absence of other debilitating diseases. In most cases with abscess formation, surgical drainage is necessary.

PREVENTION
*S. aureus* infection is transmitted primarily by direct contact. Strict attention to handwashing techniques is the most effective measure for preventing the spread of staphylococci from 1 individual to another (see Chapter 173). Use of a hand wash containing chlorhexidine or alcohol is recommended. In hospitals or other institutional settings, all persons with acute *S. aureus* infections should be isolated until they have been treated adequately. There should be constant surveillance for nosocomial *S. aureus* infections within hospitals. When MRSA is recovered, strict isolation of affected patients has been shown to be the most effective method for preventing nosocomial spread of infection. Thereafter, control measures should be directed toward identification of new isolates and strict isolation of newly colonized or infected patients. Clusters of cases may be defined by molecular typing. If associated with a singular molecular strain, it may also be necessary to identify colonized hospital personnel and attempt to eradicate carriage in affected individuals.

A number of protocols exist aimed at decolonization in patients with recurrent *S. aureus* skin infection, particularly in individuals colonized with MRSA. These often involve various combinations of decontaminating baths (hypochlorite, 1 teaspoon common bleach solution per gallon of water, or chlorhexidine 4% soap), an appropriate oral antibiotic, and nasal mupirocin. Although success is not universal, recurrent infections may be reduced, particularly when eradication is done in both patient and frequent or household contacts. Most cases of mild, recurrent disease will resolve in time without these measures.

Food poisoning (see Chapter 340) may be prevented by excluding individuals with *S. aureus* infections of the skin from the preparation and handling of food. Prepared foods should be eaten immediately or refrigerated appropriately to prevent multiplication of *S. aureus* with which the food may have been contaminated.

### 181.2 Toxic Shock Syndrome

*James T. Gaensbauer and James K. Todd*

Toxic shock syndrome (TSS) is an acute and potentially severe illness characterized by fever, hypotension, erythematous rash with subsequent desquamation on the hands and feet, and multisystem involvement, including vomiting, diarrhea, myalgias, nonfocal neurologic abnormalities, conjunctival hyperemia, and strawberry tongue.

ETIOLOGY
TSS is caused by TSST-1–producing and some enterotoxin-producing strains of *S. aureus*, which may colonize the vagina or cause focal sites of staphylococcal infection.

EPIDEMIOLOGY
TSS continues to occur in the United States in men, women, and children, with highest rates in menstruating women 15-25 yr of age. Nonmenstrual TSS is associated with *S. aureus* infected nasal packing and wounds, sinusitis, tracheitis, pneumonia, empyema, abscesses, burns, osteomyelitis, and primary bacteremia. Most strains of *S. aureus* associated with TSS are methicillin susceptible. While USA300, the predominant isolate of community-acquired MRSA in the United States, does not contain genes expressing the most common TSS superantigens, MRSA-associated TSS does occasionally occur.

PATHOGENESIS
The primary toxin associated with TSS is TSST-1, though a significant proportion of nonmenstrual TSS is caused by 1 or more staphylococcal enterotoxins. These toxins act as superantigens, which trigger cytokine release causing massive loss of fluid from the intravascular space and end-organ cellular injury. Epidemiologic and in vitro studies suggest that these toxins are selectively produced in a clinical environment consisting of a neutral pH, a high P\(_{CO_2}\), and an “aerobic” P\(_{O_2}\), which are the conditions found in abscesses and the vagina with tampon use during menstruation. The risk factors for symptomatic disease include a nonimmune host colonized with a toxin-producing organism, which is exposed to focal growth conditions (menstruation plus tampon use or abscess) that induce toxin production. It appears that some hosts may have a varied cytokine response to exposure to TSST-1, helping to explain a spectrum of severity of TSS that may include staphylococcal scarlet fever. The overall mortality rate of treated patients is 3-5% with early treatment.

Approximately 90% of adults have antibody to TSST-1 without a history of clinical TSS, suggesting that most individuals are colonized at some point with a toxin-producing organism at a site (anterior nares) where low-grade or inactive toxin exposure results in an immune response without disease.

### CLINICAL MANIFESTATIONS

The diagnosis of TSS is based on clinical manifestations (Table 181-2). The onset is abrupt, with high fever, vomiting, and diarrhea, and is accompanied by sore throat, headache, and myalgias. A diffuse erythematous macular rash (sunburn-like or scarlatiniform) appears within 24 hr and may be associated with hyperemia of pharyngeal, conjunctival, and vaginal mucous membranes. A strawberry tongue is common. Symptoms often include alterations in the level of consciousness, oliguria, and hypotension, which in severe cases may progress to shock and disseminated intravascular coagulation. Complications, including acute respiratory distress syndrome, myocardial dysfunction, and renal failure, are commensurate with the degree of shock. Recovery occurs within 7-10 days and is associated with

desquamation, particularly of palms and soles; hair and nail loss have also been observed after 1-2 mo. Immunity to the toxins is slow to develop, so recurrences can occur, especially if there is inadequate antibiotic treatment and/or recurrent tampon use. Many cases of apparent scarlet fever without shock may be caused by TSST-1-producing S. aureus strains.

**DIAGNOSIS**

There is no specific laboratory test, and diagnosis is dependent on meeting certain clinical and laboratory criteria in the absence of an alternate diagnosis (see Fig. 181-2). Appropriate tests reveal involvement of multiple organ systems, including the hepatic, renal, muscular, gastrointestinal, cardiopulmonary, and central nervous systems. Bacterial cultures of the associated focus (vagina, abscess) before administration of antibiotics usually yield S. aureus, although this is not a required element of the definition.

**Differential Diagnosis**

Group A Streptococcus can cause a similar TSS-like illness, termed streptococcal TSS (see Chapter 183), which is often associated with severe streptococcal sepsis or a focal streptococcal infection such as cellulitis, necrotizing fasciitis, or pneumonia.

Kawasaki disease closely resembles TSS clinically but is usually not as severe or rapidly progressive. Both conditions are associated with fever unresponsive to antibiotics, hyperemia of mucous membranes, and an erythematous rash with subsequent desquamation. However, many of the clinical features of TSS are usually absent or rare in Kawasaki disease, including diffuse myalgia, vomiting, abdominal pain, diarrhea, azotemia, hypotension, acute respiratory distress syndrome, and shock (see Chapter 166). Kawasaki disease typically occurs in children younger than 5 yr. Scarlet fever, Rocky Mountain spotted fever, leptospirosis, toxic epidermal necrolysis, sepsis, and measles must also be considered in the differential diagnosis.

**TREATMENT**

Recommended antibiotic therapy for TSS should include the combination of a β-lactam–resistant antistaphylococcal antibiotic (nafcillin, oxacillin, or a first-generation cephalosporin) plus clindamycin to reduce toxin production. Though TSS is most commonly caused by MSSA, clinicians should consider use of vancomycin in place of the β-lactam in areas where MRSA rates are very high, when hospital acquired MRSA is suspected, and when the clinical picture overlaps with staphylococcal sepsis. Drainage of the vagina by removal of any retained tampons in menstrual TSS and of locally infected sites in nonmenstrual TSS is important for successful treatment. Antistaphylococcal therapy and avoidance of tampon use may also reduce the risk for recurrence in menstrual TSS.

TSS often requires intensive supportive care, including aggressive fluid replacement to prevent or treat hypotension, renal failure, and cardiovascular collapse. Inotropic agents may be needed to treat shock; corticosteroids and intravenous immunoglobulin may be helpful in severe cases.

**PREVENTION**

The risk for acquiring menstrual TSS (1-2 cases/100,000 menstruating women) is low. Changing tampons at least every 8 hr is recommended. If a fever, rash, or dizziness develops during menstruation, any tampon should be removed immediately and medical attention should be sought.

**BIBLIOGRAPHY**

**181.3 Coagulase-Negative Staphylococci**

**James K. Todd**

At present, there are approximately 30 species of coagulase negative staphylococci (CoNS) affecting or colonizing humans. *Staphylococcus epidermidis*, and less commonly *Staphylococcus hominis*, *S. haemolyticus*, and others, are widely distributed on the skin and are significant causes of nosocomial infection, particularly in the bloodstream of neonatal and immunocompromised hosts, in surgical patients and those with indwelling catheters and other medical devices. *S. saprophyticus* is a common cause of urinary tract infection. *Staphylococcus lugdunensis* has been increasingly recognized as cause of potentially severe infection.

**EPIDEMIOLOGY**

In the United States, CoNS are the most common cause of hospital acquired infection, particularly in neonatal units. In many instances, growth of CoNS from clinical specimens represents contamination from skin, rather than a cause of true disease, posing significant challenges for clinicians and infection control specialists. CoNS are normal inhabitants of the human skin, throat, mouth, vagina, and urethra. *S. epidermidis* is the most common and persistent species, representing 65-90% of staphylococci present on the skin and mucous membranes. Colonization, sometimes with strains acquired from hospital staff, precedes infection; alternatively, direct inoculation during surgery may initiate infection of CSF shunts, prosthetic valves, or indwelling vascular lines. For epidemiologic purposes, CoNS can be identified on the basis of molecular DNA methods.

**PATHOGENESIS**
